Psychologic testing has shown that preschool-aged children who had prolonged uncorrected cyanotic heart disease in infancy have slightly lower intelligence quotient scores and tend to perform poorer with perceptual motor tasks than children with asymptomatic acyanotic heart disease. Early atrial corrective surgery has been demonstrated to have beneficial effects on weight and linear growth; however, the long-term effects of intense, prolonged early cyanosis are not yet fully evaluated. Although the benefits of early detection (30) and correction (31) are likely to minimize secondary end-organ damage, more recent data suggest that the Full Scale IQ scores for these children, as a group, may be lower than the normal population, and there is a higher-than-expected incidence of learning disabilities, speech and language problems, and motor delays (32–36).

Electrocardiographic Features

The usual ECG findings are right-axis deviation with right or combined ventricular hypertrophy; the findings, however, vary considerably, depending on age and anatomic and physiologic factors. The ECG in the first days of life is typically normal for age. Within weeks, however, abnormal right ventricular hypertrophy appears in most infants with IVS or small VSD. Initially, this may be identified solely by the persistence, beyond 3 to 5 days of age, of a positive T wave in the right precordial leads. Right-axis deviation predominates when the septum is intact; in contrast, one-third of infants with large VSD have

normal QRS axis for age. Left-axis deviation occurs rarely in TGA/IVS but is typical in TGA with AV septal defect types of VSD, with or without straddling tricuspid valve or right ventricular hypoplasia.

Combined ventricular hypertrophy is present in about 60% to 80% of patients with large VSD. These ECG patterns are modified by LVOT stenosis or increased pulmonary vascular resistance. A Q wave in V6 is usually present (70%) in TGA with large VSD but is infrequent (15%) when the ventricular septum is intact (37). Isolated left ventricular hypertrophy is rarely encountered and suggests TGA with VSD, straddling of the tricuspid valve, and associated hypoplasia of the right ventricle.

Dysrhythmias are rarely noted in the newborn period, but short periods of bradycardia and junctional rhythm may be seen in 24-hour ambulatory ECG recordings. Atrial flutter may be seen during and after BAS.

Radiologic Features

Roentgenographic findings may provide diagnostic assistance (Fig. 49.19); however, in the neonate particularly, the findings may be normal. In the neonate with TGA/IVS, the diagnostic triad includes (a) oval or egg-shaped cardiac silhouette with narrow superior mediastinum, (b) mild cardiomegaly, and (c) increased pulmonary vascular markings.

Transposition of the Great Arteries with Intact Ventricular Septum

In the first few days and weeks of life, the chest roentgenogram may appear normal. The heart is usually slightly enlarged, but one-third of the neonates have no cardiac enlargement. Pulmonary vascular markings are considered normal in from one-third to one-half the neonates seen, and the typical oval-shaped silhouette is not present in one-third to one-half of these infants. The vascular pedicle or superior mediastinal silhouette is narrow because of the usual anteroposterior relationships of the great arteries and the hypoplasia of thymus tissue associated with cyanosis and stress. Right aortic arch is relatively uncommon: 4% in patients with TGA/IVS and 11% in patients with TGA/VSD (38,39).

After the first few weeks of life, cardiac enlargement may become evident, and the pulmonary vascular markings appear increased in almost every infant with TGA without LVOTO. In some neonates, however, even following adequate BAS, the pulmonary vascular markings do not appear increased initially,

Figure 49.19. Frontal chest roentgenograms in three neonates with TGA/IVS and no significant PDA at 1 day of age. Note variations in cardiac size, shape, and pulmonary vasculature.

and these infants often have persistent low systemic arterial oxygen saturation. Such observations support the hypothesis that functionally the pulmonary vascular bed may remain relatively vasoconstricted, and the resultant inadequate increase in pulmonary blood flow minimizes the functional effectiveness of an adequate BAS. In the past, when surgical repair usually was delayed for months following BAS, clinical deterioration sometimes occurred and was characterized by increasing cyanosis with progressive diminution in pulmonary vascularity secondary to progressive dynamic LVOTO. Recognition and assessment by echocardiography are important for this subset of infants.

Transposition of the Great Arteries/Large Ventricular Septal Defect

The pulmonary vascular markings in infancy appear particularly prominent when a large VSD is present with low pulmonary vascular resistance, and the cardiac silhouette is usually considerably larger than seen in TGA/IVS. If advanced pulmonary vascular obstruction is present (in older infants and children), the hilar vessels are enlarged, but the peripheral pulmonary vessels appear small and constricted; the left cardiac border is often grossly distorted by a dilated pulmonary artery trunk. Pulmonary vascular markings remain increased in the face of moderate LVOT stenosis, and only severe obstruction or atresia is associated with diminished pulmonary vascular markings.

Echocardiographic Features

In the current era, echocardiography has become the diagnostic method of choice in the patient with TGA (Fig. 49.20). Subcostal imaging provides a flexible acoustic window that allows wide angulation and rotation of the transducer beam to optimize simultaneous visualization of the great arteries (ascending aorta and main pulmonary artery with its primary branches) and their respective ventricular connections. Additional imaging from the apex (four-chamber view) is useful in establishing the identity of the posterior vessel as the pulmonary artery from its branching morphology. Suprasternal and high parasternal views enable the aorta to be traced arising from the right ventricle to the arch and its branches. Spatial orientation of the great arteries and the origin and proximal segments of the coronary arteries can be viewed on parasternal and short-axis scans at the base of the heart. Echocardiography can diagnose most of the important associated anomalies with a high degree of accuracy, including size, number, and location of VSDs; anatomic type of LVOTOs; form and function of tricuspid and mitral valve anomalies; and outlet septum malalignment defects. Imaging can be used to guide catheter placement and movements during BAS (Fig. 49.21) and to assess the anatomic adequacy of the septostomy.

In the current era, echocardiography has assumed the primary role in determining the candidacy of a neonate with simple TGA for arterial switch, even to the extent of replacing cardiac catheterization in many centers. Routine obstetric fetal echocardiography may lead only to the prenatal diagnosis of TGA in those patient subgroups who have associated large VSD, common AV septal defect, or severe outflow tract obstruction where the usual four-chamber screening examination reveals the presence of a serious malformation and leads to a more extensive (cardiac-expert) examination of the great vessel origins. Conversely, for TGA with IVS, an obstetric screening examination frequently does not readily identify the malformation and presently may not influence clinical management or referral programs. The diagnosis of TGA (even with IVS) can readily be made, however, by specialized fetal echocardiography. Perhaps the greatest advantage of prenatal

diagnosis is the ability to deliver the infant in an obstetric facility with the expectation of cardiac disease, institution of PGE₁ therapy, and prompt transfer to a specialized cardiac facility before clinical deterioration may take place.

Cardiac Catheterization

Cardiac catheterization with BAS in some centers continues to assume an emergency priority, particularly for the neonate with poor intercirculatory mixing. In any event, successful management includes prompt initiation of any indicated supportive medical therapy, such as airway protection, oxygen, acid-base correction, PGE₁ infusion, antibiotics, and, in some patients with large intercirculatory shunts, inotropic support and diuretics. Increasingly, catheterization with BAS is not routinely undertaken in many centers where the neonate with TGA often proceeds directly to primary arterial switch correction during the first few days of life. A complete echocardiographic diagnosis (and possible simultaneous balloon septostomy) with interim supportive PGE₁ infusion may be all that is necessary prior to surgery. Some centers will not perform septostomy at all unless there is echocardiographic evidence of a restrictive foramen ovale or absence of a significant rise in arterial PO₂ on initiating prostaglandin infusion.

Cardiac catheterization, angiography, BAS, and meaningful physiologic information can be obtained safely only if optimum techniques are expertly and judiciously employed using percutaneous femoral vein entry, umbilical vein catheterization, or (rarely) direct femoral vein cutdown. In the unstable neonate with poor mixing, it is advisable to proceed with therapeutic BAS promptly before attempting more extensive hemodynamic and angiographic investigations.

Cardiac catheterization remains an important adjunct in the diagnostic evaluation of infants with echocardiographic diagnoses of more complex forms of TGA. Additional observations on the following items are important in planning appropriate palliative or corrective surgery: pulmonary artery pressure; pulmonary blood flow (and vascular resistance); coronary artery anatomy; morphologic details of pulmonary or subpulmonary obstruction; VSD number, site, and size; great-vessel alignments in relation to the VSD and outlet septum; and type and severity of aortic arch abnormalities. In such cases, when surgical palliation (e.g., pulmonary artery banding, septectomy) is planned or repair is electively delayed, BAS should be strongly considered, even in patients with large VSD, to improve interatrial left-to-right shunting (effective systemic blood flow) to decrease left atrial pressures.

Entrance into the pulmonary artery in the neonate is usually difficult, time-consuming, and occasionally traumatic. Aside from the value of these measurements for later comparisons, such measurements are usually not essential for management in the neonate or infant as the peak systolic pulmonary arterial and left ventricular pressures are usually equal in neonates, except when there is significant subpulmonary stenosis or pulmonary atresia, both of which can be easily recognized by echocardiography or angiography.

A deflated balloon-tipped catheter can be directed across the interatrial communication to the left atrium, where the balloon is inflated. The catheter usually advances rapidly to the left ventricle, either to form a curve with the tip directed to the outflow tract or to become wedged in the apex. If the latter occurs, the catheter tip is best withdrawn to the mitral level and then advanced and withdrawn slowly with lesser degrees of balloon inflation until the catheter tip is carried into the LVOT, where it then can be advanced rapidly into the pulmonary artery. Tip-deflecting wires are extremely helpful in directing the balloon toward the LVOT; the catheter then may

Figure 49.20. Two-dimensional echocardiographic images in 1-day-old with TGA/IVS. **A:** Subcostal view demonstrates left ventricle (LV) and unobstructed LVOT aligned (connected) with normal pulmonary (potential neo-aortic) valve, main (MPA), right (RPA), and left (LPA) pulmonary arteries. A large PDA is seen (on prostaglandin E1 infusion). **B:** Parasternal short-axis view demonstrates slightly oblique interrelationship of the great arteries consistent with TGA [S,D,D] (AO). LA, left atrium; PA, pulmonary artery. **C:** Parasternal long-axis view confirms discordant ventriculoarterial connection: the pulmonary trunk by its abrupt posterior turn shortly distal to the pulmonary valve, and (in other planes of this echo view) the aorta by the origin of the brachiocephalic artery. **D:** Origin and proximal branches of the left coronary artery in the usual coronary artery anatomy for TGA (see also Fig. 49.7). Note origin of left main coronary (LM) from left/posterior facing sinus and its bifurcation into proximal left circumflex (LCX) and anterior descending (LAD) branches. The right coronary artery, in another echo plane, arises from the posterior right aortic sinus. **E,F:** Echocardiographic images obtained at postoperative examination 1 year after surgery (arterial switch at 13 days of age) shows moderate dilation of the neo-aortic root. Right (RCA) and left main (LM) coronary arteries show no stenosis or obstructive kinking in the proximal segments. RVO, right ventricular outflow.

be “peeled off” the deflecting wire and advanced into the pulmonary artery.

In patients with significant inlet or outlet VSDs, it may be possible to manipulate the catheter directly from the right ventricle through the VSD into the pulmonary artery, although this may induce heart block. If the pulmonary artery is not entered, pulmonary-vein wedge pressures should be obtained; if they are normal, it is unlikely that the pulmonary artery pressure is elevated. Catheterization findings are consistent with the detailed discussions under the section on Physiology and with the classification schema (Table 49.2).

In the newborn with TGA/IVS and markedly inadequate intercirculatory mixing (group I), the oxygen saturation in the

vena cava may be as low as 20%, although usually it is about 40%. There is usually only a small increase of 5% to 10% in the right atrium and right ventricle; the systemic arterial saturation is quite similar to that in the right ventricle. Pulmonary venous saturation is generally normal, and there may be a 4% to 8% decrease in the left atrium or left ventricle. A marked combined respiratory and metabolic acidosis, along with severe hypoxemia, is a hallmark of TGA/IVS with poor mixing.

In the infant with a large intercirculatory communication (group II, TGA/VSD), the vena caval saturations are modestly reduced, and there is usually an increase in oxygen saturation at the atrial level of 5% to 10% as a result of interatrial

Figure 49.21. BAS performed in newborn with 2-D echo imaging to guide catheter placement and septostomy balloon withdrawal from (A) left atrium (LA) to (B) right atrium (RA). Arrows delineate balloon.

shunting. A large increase in oxygen saturation is observed in the right ventricle, to levels of 70% to 85%, and similar levels are noted in the aorta. The pulmonary venous oxygen saturation rarely may be reduced because of left atrial hypertension and pulmonary edema. Similar oxygen saturations are noted in the left atrium and left ventricle, but the pulmonary artery saturation may be somewhat lower than that in the left ventricle due to some preferential pulmonary artery streaming from the interventricular right-to-left shunt. The distinguishing feature of “transposition physiology” is that the oxygen saturation in the pulmonary artery is always higher than in the aorta; however, with extensive intracardiac mixing, the saturations may be quite similar. In the absence of an adequate atrial communication, left atrial pressures may be quite elevated, up to 20 mm Hg or more, with quite prominent V waves. With a large VSD, the left and right ventricular systolic and end-diastolic pressures and pulmonary and aortic systolic pressures may be essentially identical; the pulmonary arterial end-diastolic and mean pressures, however, are commonly lower than the systemic levels, reflecting the lower pulmonary vascular resistance.

When there is LVOT stenosis associated with a large VSD (group III), the findings depend on the severity of the pulmonary outflow tract obstruction. When the obstruction is severe, along with a small or closed ductus arteriosus, the systemic arterial oxygen saturation may be quite low (30% to 50%), and the clinical findings are similar to those in tetralogy of Fallot with severe pulmonary stenosis or atresia.

Angiocardiography

When indicated, selective cardiac chamber and great vessel angiographic injections should be performed to identify or confirm the echocardiographic diagnoses and associated cardiac defects. In the current era, echocardiography provides superior imaging of many of these abnormalities, particularly those associated with the AV and semilunar valve structures and the ostia and proximal course of the coronary arteries.

In the lateral angiogram in TGA/IVS, the aorta usually forms a wide open arch with the ascending portion proceeding far ventrally. The aortic valve cusp level is higher (fourth to fifth thoracic vertebral level) than in the normal heart (seventh thoracic vertebral level) and reflects the well-developed subaortic conus characteristic of TGA. Deviation occurs particularly when a large VSD with atypical conal morphology (bilateral conus or deficient conus) is present or with

the rare form of posterior transposition. The ascending aorta is typically anterior and to the right of the pulmonary artery in an oblique relationship; the large main pulmonary artery arises slightly to the left and definitely posterior to the aorta.

Variations and some ambiguity may arise when angiographically the transposed aortic valve appears to lie directly anterior to the transposed pulmonary valve and more particularly when the transposed aortic valve lies anterior and slightly to the left of the transposed pulmonary valve (6% to 14%). The physiologic findings in the latter instance again are those of physiologically uncorrected TGA, but the segmental findings are TGA {S,D,L}, AV-concordant connection, that is, situs solitus of viscera and atria (S), ventricular D-loop (D), and an apparent L-position of the semilunar valves (L) (Fig. 49.22A–D). This configuration is to be differentiated, particularly in the anteroposterior angiographic view, from the usual physiologically corrected TGA, {S,L,L} TGA AV discordant connection (Fig. 49.22E–H).

Identification and localization of the conal musculature and semilunar–AV valve relationships can be helpful in analyzing the more complex variations. The tricuspid valve is best visualized by using selective right ventricular injection in the frontal or right anterior oblique views by noting intra-atrial bulging of the leaflets during ventricular systole and during diastole by the negative silhouette of the orifice as nonopacified blood enters the ventricle. Continuity of the anterior leaflet of the mitral valve with the pulmonary valve is best visualized in the four-chamber long-axial or left anterior oblique views in diastole when the anterior leaflet is noted to form the posterior wall of the LVOT. In the frontal view, the line of attachment of the posterior mitral valve leaflets can best be seen in diastole. Straddling or overriding tricuspid valve with VSD must be suspected whenever hypoplasia of the right ventricle is observed. Levoposition (“juxtaposition”) of the right atrial appendage frequently accompanies this constellation of anatomic findings.

The number, site, and size of VSD(s) can be well visualized by angiography, particularly when an appropriate long axial or hepatoclavicular four-chamber oblique (rather than lateral) view is used (Figs. 49.9, 49.10A, and 49.11A). In many instances, the VSD represents an additional but uncomplicated anatomic component of the surgical repair. When there are various types of atypical conus associated with malalignment or straddling AV orifices, valve leaflets, or their attachments, however, foreknowledge of the precise size and location of the VSD and its relationship to the semilunar and AV valves is

Figure 49.22. Angiograms (A–D) illustrating variant leftward position of aortic valve in 4-year-old with TGA {S,D,L} following intra-atrial (Mustard) repair. **A:** Frontal view, selective transvenous injection into left-sided morphologically left ventricle (LV). **B:** Frontal view, after pulmonary circulation and opacification of new pulmonary venous atrium (PVA), right-sided, morphologically right ventricle (RV) and left-malpositioned aortic (Ao) valve. **C:** Lateral view of (A). **D:** Lateral view of (B). PVAa, anterior segment; PVAp, posterior segment of pulmonary venous atrium. Angiograms (E–H) illustrating leftward position of aortic valve in 4-year-old with TGA {S,L,L}. **E:** Frontal view, selective injection into right-sided morphologically left ventricle (LV). **F:** Frontal view, after pulmonary circulation and opacification of left atrium (LA) and left-sided morphologically right ventricle (RV) and left positioned aortic (AO) valve. **G:** Lateral view of (E). **H:** Lateral view of (F).

mandatory. The four-chamber hepatoclavicular projection is particularly useful for profiling the posterior inlet component of the ventricular septum. Long axial oblique views are useful for demonstrating the various outlet septum malalignment abnormalities, including the VSD and right and left ventricular outlet obstructions.

The various forms of LVOT stenosis can be best discriminated angiographically by long axial left ventricular views. Small peak systolic pressure differences (<20 mm Hg) between left ventricle and main pulmonary artery have been attributed to a “functional” stenosis of the pulmonary valve and outflow tract, similar to that observed in patients with secundum ASD with high pulmonary blood flow. In TGA/IVS, however, such systolic pressure differences also may be associated with a recognizable systolic septal bulge abnormality. Minor degrees of abnormal protrusion of the upper muscular ventricular septum into the LVOT in systole are subtle but can be appreciated angiographically in the lateral and left anterior oblique views. Occasionally, the entire ventricular septum encroaches convexly and posteriorly during systole, and the left ventricle appears small and flattened (“pancaked”) (Fig. 49.4).

A more obvious angiographic subpulmonary ridge-like obstruction is associated with somewhat larger LVOT pressure differences and reflects a subvalvar fibrous muscular ridge obstruction, often with an underlying abnormal septal bulge. This fibromuscular ridge is probably a systolic impact lesion and angiographically appears as a prominent irregular curvilinear radiolucent line during systole in the region of the mitral valve. The ridge is often most prominent medially and may demarcate sharply a small subpulmonary vestibule (Fig. 49.5B,D). Isolated pulmonary valve stenosis is infrequent

as a major lesion, but thickened valve cusps may be observed. The fibromuscular tunnel-type stenosis can best be recognized in the left long-axial oblique view as an extensive, narrow, fixed restrictive passage extending from above the VSD for some length toward the pulmonary valve. This form is commonly associated with a VSD with a posterior malalignment of the conal septum, with crowding of the LVOT (Figs. 49.8A and 49.10A). Subpulmonary obstruction resulting from aneurysm of the membranous ventricular septum or redundant tricuspid valve tissue displaced into the LVOT may be recognized by careful angiographic assessment (Fig. 49.12A). Persistent subpulmonary obstruction also can be caused by anomalous septal attachments of straddling mitral valve tissue.

Malalignment defects of the ventricular outlet septum also may be associated with anterior–rightward septal deviation, which causes distinct anatomic, but less frequently hemodynamic, right ventricular outflow tract obstruction (Fig. 49.8B); with this abnormality, distal systemic circulation malformations such as coarctation or interruption of the aorta should be anticipated and investigated by angiography and echocardiography.

Although the coronary artery anatomy sometimes may be outlined from a right ventriculogram, better visualization is achieved by selective transvenous coronary angiography or antegrade aortic root angiography with distal balloon occlusion of the ascending aorta. Using this technique, a balloon angiographic catheter (with injection holes proximal to the balloon), introduced transvenously, is positioned in the ascending aorta proximal to the brachiocephalic arteries so that the side holes are approximately 1 cm above the aortic valve. The balloon is inflated with carbon dioxide and

stabilized in the ascending aorta. During cineangiography, between 0.5 and 1.0 mL/kg of contrast medium are injected over approximately 1 second, and the balloon is deflated immediately after the injection. Inflation of the balloon during injection allows contrast medium to be preferentially directed toward the aortic root and coronary ostia.

Mandell et al. (40) combined balloon occlusion aortography with extreme caudal angulation of the anterior-posterior camera, producing the so-called laid-back aortogram (Figs. 49.23 and 49.24). This is perhaps the most anatomically precise angiographic technique for the preoperative assessment of the coronary arteries in TGA because it provides visualization of both the proximal ostia and distal distribution of the coronary arteries in the same plane of view (see section on "Morphology").

Balloon Atrial Septostomy

In the newborn <48 to 72 hours of age, the umbilical vein has been used successfully for BAS as well as diagnostic catheterization. More commonly, percutaneous needle and catheter sheath placement is used to gain access to the femoral vein. Successful, adequately sized rupture of the septum primum flap to enlarge the interatrial opening is dependent on both structural-design elements of the balloon catheter and procedural techniques.

The catheter should be advanced across the foramen ovale into the left atrium or a pulmonary vein and the position of the tip established with certainty in the left atrium prior to proceeding. Location of the catheter tip is established most readily by echocardiography or by using fluoroscopy to visually confirm the posterior position of the tip in the lateral or left anterior oblique view or entry of the catheter into a pulmonary vein. Once the position is verified, the balloon is inflated with diluted angiographic contrast medium to at least 12- to 15-mm diameter and then rapidly withdrawn across the atrial septum with an abrupt, short tug, "like a backhand in squash" (Keane JF, *personal communication*). The balloon and interatrial septum are displaced toward the inferior vena cava, and the septum primum flap of the fossa ovalis is ruptured as the balloon is carried in a single movement from the left atrium to the right atrial-inferior vena caval junction. The catheter should be advanced immediately and the balloon pushed cephalad out of the inferior vena caval orifice into the right atrium toward the superior vena cava to verify crossing the septum and to avoid obstruction to inferior vena caval return while the balloon is being deflated. This same procedure should be repeated several times with increasing balloon volumes, so that withdrawal of the balloon, inflated tensely to a diameter of at least 15 mm, is achieved without much resistance being perceived at the atrial septum level. Slow or gentle withdrawal of the balloon from the left-to-right atrium is considered by some to

Figure 49.23. Upper panel: Position of frontal C-arm with extreme caudal angulation of the tube. The lateral tube, necessary for balloon positioning, is not shown. Lower left panel: View of heart and balloon position as "seen" by lateral image intensifier. Solid arrow in right upper corner shows "viewpoint" of frontal camera when it assumes its caudal angulation. Lower right panel: Caudal view of heart and coronary arteries as displayed by frontal cine camera. An example of coronary course in anterior-posterior (A) and side-by-side (B) great arteries is shown. Circ, circumflex coronary artery; LAD, left anterior descending artery; RCA, right coronary artery. (From Mandell VS, Lock JE, Mayer JE Jr, et al. The "laid-back" aortogram: an improved angiographic view for demonstration of coronary arteries in transposition of the great arteries. *Am J Cardiol* 1990;65:1379-1383, with permission.)

Figure 49.24. A: Caudal view in a patient whose great arteries are side by side with inverted right and circumflex coronary arteries (see Fig. 49.7). From the anterior-facing sinus, a coronary artery originates and gives rise to the left anterior descending artery (*double arrow*), which crosses anterior to the pulmonary artery and a small right coronary artery (*single arrow*). From the posterior facing sinus arises a dominant circumflex artery (*triple arrow*), which courses behind the pulmonary artery and supplies the lateral, posterior, and inferior walls of the left ventricle. B: Lateral view of the same showing ideal balloon position and occlusion of the aorta at time of injection. (From Mandell VS, Lock JE, Mayer JE Jr, et al. The “laid-back” aortogram: an improved angiographic view for demonstration of coronary arteries in transposition of the great arteries. *Am J Cardiol* 1990;65:1379–1383, with permission.)

be counterproductive because it causes stretching rather than tearing of the septum primum flap with temporary functional rather than permanent anatomic enlargement of the foramen ovale defect.

Cardiac complications of the procedure are uncommon when the aforementioned precautions are observed, but the operator must be knowledgeable and skilled to avoid atrial wall, pulmonary vein, or inferior vena caval perforation or tears or AV valve damage. Other injuries that have been reported include damage to the inferior vena cava, which probably can be minimized by using an adequately inflated balloon so that it is not pulled deep into the inferior vena cava. Patients may develop complete heart block, although it is typically self-limited and rarely requires long-term pacing. Intracardiac rupture of the balloon occurs infrequently, but it is important to avoid introducing air bubbles during inflation with the contrast medium to prevent air embolization. Rubber fragmentation and embolization from a ruptured balloon have been virtually abolished by new materials and fabrication techniques. A recent report raised the important question of CNS complications such as stroke or ischemia identified in critically ill patients with TGA undergoing urgent septostomy (41). In this retrospective review, it was difficult to separate out the CNS effects of the profound hypoxemia leading to the need for urgent intervention, from the CNS effects of the intervention itself. Nonetheless, potential CNS complications should factor in the decision to perform septostomy, especially in nonemergent situations (see below). Deflation failure of the balloon in the right atrium after septostomy, a rare complication in the past, has been obviated by the newer fabrication techniques. The inability to deflate the balloon using the syringe can be managed without surgery, however, by carefully inserting the sharpened, stiff end of a guidewire along the catheter shaft and rupturing the balloon.

If levoposition of the right atrial appendage (juxtaposition of atrial appendages) is present, the catheter tip, still in the right atrial appendage, may appear falsely to conform to conventional criteria for left atrial positioning. With this anomaly, the right atrial appendage is more posterior than normal and occupies the left upper heart border in the anteroposterior view. The operator should suspect levoposition of the right atrial

appendage if the catheter tip cannot be directed into a pulmonary vein or pass quite as much posteriorly as usual. Selective right atrial angiograms, or preferably a precatheterization echocardiographic examination, will verify the diagnosis.

In the neonate, satisfactory rupture of the septum primum flap covering the fossa ovalis is nearly always affected by proper BAS technique. In older infants, particularly those with TGA/VSD, a thickened interatrial flap may preclude successful balloon catheter septal rupture. If necessary, a catheter equipped with an extendable blade may be used to enlarge the interatrial communication prior to septostomy. Finally, in patients with a markedly thick atrial septum, a new defect (separate from the foramen ovale) can be created with a transseptal needle and dilated with an 8- to 15-mm-diameter balloon angioplasty catheter (static balloon septoplasty). A second hole is recommended because long-term dilation of the true foramen ovale has been unsuccessful in most cases (Lock JE, *personal communication*).

TREATMENT

Consideration of optimal treatment choices for the various subsets of patients with complete transposition must integrate the current information available on over 50 years' experience with atrial level repair and 30+ years of arterial level repair. Abundant early and midterm postoperative observations warrant cautiously optimistic support for the choice of an arterial switch repair for newborns with nearly all forms of TGA. This trend is reflected in data from a multi-institutional study showing an increase in arterial switch repair from 40% of the eligible TGA study population in 1985 to 80% in 1990.

Palliative Therapy

In the past, the keystone to improved survival and eventual corrective surgery has been the successful application of palliative procedures: BAS, surgical septectomy, partial venous correction, pulmonary artery banding, and systemic–pulmonary shunts.

Balloon Atrial Septostomy

Accumulated experience over the past four decades clearly has established the value of BAS for the initial management of the severely hypoxemic neonate with TGA: Survival for the first month of life improved from 20% before septostomy was introduced to as high as 95% afterward. Accordingly, BAS was performed in neonates as the first step in any management program for patients destined to have atrial repair procedures later in infancy. In the past two decades of the widespread adoption of an early arterial switch, coupled with the potential complications of “routine” septostomy (41), many centers have chosen to perform a BAS only in cases of profound hypoxemia, or in cases when corrective surgery must be delayed, and in routine cases, maintaining acceptable oxygenation with a PDA, a native septal communication, and PGE₁.

In the past, when atrial repair surgery was electively delayed, particularly beyond the first year of life, a significant interval of morbidity and mortality occurred from complications, including cerebrovascular accidents, progressive pulmonary vascular disease, myocardial failure, and intravascular thrombosis. A multi-institutional protocol followed up on neonates with simple TGA entering the study at <15 days of age (Fig. 49.25) (37). Among the 106 patients assigned to an atrial switch repair (median age at repair: Senning, 2.9 months; Mustard, 6.7 months), five deaths occurred before repair and were associated with hypoxia or heart failure. No deaths before repair occurred among 76 patients assigned in this study to an arterial switch repair protocol (median age at repair: 6 days).

Prostaglandin E1 (in Conjunction with Management Protocol for Early Neonatal Arterial Switch Repair with or without Balloon Atrial Septostomy)

BAS: CURRENT INDICATIONS, TIMING, AND ANALYSIS OF RISK/BENEFIT

It has become apparent that if arterial switch repair is to be performed early after birth, most cyanotic neonates with TGA/IVS benefit from interval prostaglandin-induced increased

Figure 49.25. Cumulative frequency distribution of patient age at the time of planned-executed repairs according to the type of repair from a 20-institution cooperative protocol study (Congenital Heart Surgeons Society, 1985, 1986). No deaths occurred before repair of patients assigned to an arterial switch protocol (median age at surgery, 6 days), whereas 5% of patients assigned an atrial switch protocol died before repair. (From Castañeda AR, Trusler GA, Paul MH, et al. and the Congenital Heart Surgeons Society: the early results of treatment of simple transposition in the current era. *J Thorac Cardiovasc Surg* 1988;95:14–27, with permission.)

arterial oxygen saturation even without BAS. For these neonates, a prostaglandin infusion may be instituted as soon as feasible, including during transport to the cardiac surgical center, even before the diagnosis has been confirmed echocardiographically. Some neonates will not improve following the institution of PGE₁, suggesting inadequate mixing due to a restrictive foramen ovale. With an inadequate interatrial opening, the markedly increased pulmonary blood flow resulting from the prostaglandin infusion can lead to deleterious increased pulmonary congestion, and BAS (bedside echocardiography or cardiac catheterization–fluoroscopy) may be required on an urgent basis in this subgroup.

But for approximately 85% to 90% of neonates with TGA, an electively timed arterial switch operation (with or without concomitant procedures) is the surgical procedure of choice. Despite this general agreement among cardiologists and surgeons, there is surprisingly little consensus regarding the optimal timing of the procedure, and hence, the role of “routine” BAS and continuation of PGE₁ in these patients is very institution dependent. In a recent meta-analysis in 2012, BAS frequency was 22.4%, with reported rates ranging from 20% to 75% (42).

Excluding the subgroup with TGA and profound hypoxemia from poor intercirculatory mixing—in whom an emergent BAS is the mainstay of the initial stabilization—many babies are scheduled for surgery on a “semi-elective” basis if oxygen saturations are acceptable and the baby is without symptoms. On the one hand, there are potential benefits of waiting 4 to 7 days before an arterial switch operation such as to allow the baby to make an effective transition from the fetal to the neonatal circulation, allow pulmonary vascular resistance to fall, allow some improvement in kidney and liver function to occur, to begin enteral nutrition, to evaluate for any additional congenital anomalies, and to be sure the family understands the risks and benefits of the proposed surgery. While these are “potential” benefits for the baby and family, one must also be cognizant of the “risks” that accompany a delay in surgery, with or without BAS.

If surgery is not performed immediately after birth, the two most common strategies employed are to (i) maintain an intravenous infusion of PGE₁ (usually at low doses of 0.01 to 0.02 $\mu\text{g/kg/min}$ to avoid some of the side effects including apnea, fever, and hypotension) or (ii) perform a BAS and discontinue the PGE₁, accepting lower oxygen saturations with a small or closed ductus arteriosus, but with improved diastolic blood pressure and less symptoms of heart failure from the large ductus. In fact, even with strategy ii above, only the minority of patients actually remained off PGE₁ until surgery despite a “successful” BAS (43). This group was also unable to identify any patient- or procedure-related factors that predicted the ability to remain adequately oxygenated when not receiving PGE₁.

The decision-making process involves a complex interaction between the choice of day of surgery and whether the neonate should undergo a BAS with discontinuation of PGE₁ or should “just wait” while maintaining ductal patency on PGE₁. The cardiac risks of BAS are described above; however, there are conflicting data in the literature regarding the acute risk to the central nervous system from a BAS, with some single center reports and one large registry analysis suggesting that embolic brain injury is related to BAS, while other studies and a separate registry showed no increased risk stroke (41,42,44–48).

From a whole-body perspective, maintaining a widely PDA results in a higher systemic saturation of oxygen but in a “steal” of systemic cardiac output into the lungs. Although the oxygen saturation may be in the “acceptable” range, this left-to-right shunt may in fact result in worse tissue delivery of oxygen in some patients. The pulse pressure is typically wide,

and this diastolic runoff causes worse tissue oxygen saturation resulting in potential ischemia, specifically to the brain and gut.

There may be a “false sense of security” in the preoperative baby with TGA who has little to no symptoms and adequate oxygen saturation on an infusion of PGE₁. During the waiting period, the baby is at risk for “paradoxical embolus” from an peripheral IV catheter to the central nervous system due to the uncorrected circulation, and there are increasing data showing an increased risk of infection, medical errors, and increased cost associated with increased length of stay, which a delay in surgery will cause. However, most importantly, the “reassuring” peripheral oxygen saturation may be associated with paradoxically low oxygen delivery, particularly to the brain. Measurements of cerebral venous oxygen saturation have been invasively sampled during cardiac catheterization in children who were both cyanotic and acyanotic (49–51), and noninvasively in children with right-to-left shunt lesions. In all of these situations, direct measurements of cerebral venous oxygen saturation were significantly lower than would have been predicted from the arterial or “mixed venous” oxygen saturation alone, and the babies with the lowest delivery of oxygen to the brain were those with the combination of arterial hypoxemia and a runoff lesion, either a PDA or a systemic to pulmonary shunt—exactly the situation in the preoperative neonate with TGA and a PDA. Consistent with these observations, there are evolving data demonstrating *increased* central nervous system injury—particularly to the white matter—if an arterial switch operation is delayed even by days, particularly if accompanied by hypoxemia (45). In addition, recent follow-up neurodevelopmental outcome studies in infancy and beyond suggest that earlier elimination of hypoxemia may contribute to improved motor outcomes and brain growth in certain subgroups of patients (52).

Based on currently available information, at The Children’s Hospital of Philadelphia, we have adopted a neuroprotective strategy in TGA of an early arterial switch operation (2 to 3 days of age if possible), with BAS performed if there is an anticipated delay beyond this time frame, and/or oxygen saturations are <80% despite PGE₁. In neonates receiving a BAS, the PGE₁ is then discontinued and not restarted unless there are symptoms of respiratory compromise or consistent peripheral oxygen saturation of <70% (with a small or closed PDA). With this approach in the past 2 to 3 years, preliminary data suggest a significant reduction in the incidence of preoperatively identified white matter injury compared with historical controls, but further work is necessary to confirm these preliminary data and rule out confounding factors always inherent when utilizing historical controls.

In the author’s opinion, there is little benefit (and accumulating risk) in not repairing a newborn with TGA and typical transposition physiology—especially with an open ductus arteriosus. As soon as there is evidence of a fall in pulmonary vascular resistance (usually seen by Doppler at the ductus within 24 to 48 hours) and there are no noncardiac contraindications to surgery, the baby is scheduled for the next available surgical date.

At our institution and elsewhere, there is incomplete agreement on physiologic criteria for satisfactory post balloon septostomy improvement. Obviously, clinical stabilization and decreased hypoxemia must occur. Excluding poor technical performance, a number of anatomic and physiologic factors may be responsible for unsatisfactory improvement. The fossa ovalis may be relatively small, or the valve of the foramen ovale may be quite thick, particularly in older infants and those with a large VSD. Repeat BAS for complete TGA is rarely effective, and only in a few selective cases is catheter-blade atrial septostomy indicated. 2-D echocardiographic imaging of the interatrial septum, augmented with Doppler or color techniques, can readily establish the anatomic and physiologic results of

balloon septostomy. In general, adequately palliated neonates have an interatrial defect at least 5 to 6 mm in diameter resulting from the septostomy maneuver. Nevertheless, despite the presence of adequately sized anatomic communications, inadequate circulatory mixing and disappointing clinical improvement have been noted in some infants. It has been postulated that in such cases, a delayed decrease in the pulmonary vascular resistance, with consequent low pulmonary blood flow and left atrial volumes and pressures, at times may result in inadequate interatrial mixing (see also section on “Fetal and Perinatal Physiology”).

Surgical Creation of Atrial Septal Defect

The Blalock-Hanlon operation or one of its modifications was a widely applied palliative surgical procedure for TGA in the past, but it now assumes the position of a historical footnote. An interatrial septal defect is created by excising the posterior aspect of the interatrial septum in a relatively simple closed heart procedure that can be performed rapidly on even the smallest infant (Fig. 49.26). The Blalock-Hanlon operation (closed-heart) and atrial septectomy (open-heart) produced systemic arterial oxygen saturation levels modestly higher than BAS; mean systemic arterial oxygen saturation levels range as high as 79%, and these increases were well maintained for long periods. Although early in the experience operative, mortality rates approached 30%, later series reported mortality risks <3% to 5%. Postoperative atrial dysrhythmias were infrequent and usually transient. Palliative Blalock-Hanlon or atrial septectomy procedures are rarely performed in the present era as a result of the trend toward earlier atrial and neonatal arterial repairs.

Partial Venous Return Repair (Baffles)

Historically, in the 1950s, a partial physiologic repair was proposed and achieved by connecting the inferior vena cava to the left atrium with a homograft or synthetic conduit and concurrently detaching the right pulmonary veins and directly transferring them to the right atrium. This palliative operation then results in an obligate, effective shunt at the atrial level. Subsequently, some of these patients had a modified Mustard type of atrial repair to achieve complete physiologic correction.

Pulmonary Artery Banding

Transposition associated with large VSD without LVOT stenosis, if untreated, is complicated by two major problems: heart failure and pulmonary vascular disease. Surgical constriction of the pulmonary artery can provide effective palliation for both these complications in infants and, until the arterial repair era, was commonly performed in early infancy. Although early corrective surgery with arterial switch and VSD closure is currently the procedure of choice, pulmonary artery banding in the neonatal period may be indicated, when complex, multiple VSDs are present or there are coexisting medical conditions that cause a delay in surgery to later in infancy.

Operative mortality for banding in the newborn period historically should be in the range of 5% or less. The pulmonary artery in infants with TGA in general banded more loosely than in infants with normally related great arteries because TGA pathophysiology requires a somewhat higher pulmonary blood flow for optimum intercirculatory mixing. Hemodynamically important subaortic stenosis may develop following pulmonary artery banding, although the patient population who receive palliative pulmonary artery banding includes patients with anterior malalignment types of VSDs in whom subaortic obstruction is common and occasionally progressive.

Figure 49.26. Blalock-Hanlon operation. A: Clamp placed across both atria (RA, LA) and right pulmonary veins (RPV) in the region of the interatrial sulcus. B: Excision of posterior portion of atrial septum. C: Closure of atrial incision with resultant surgically created ASD. (Modified from Cooley DA, Hallman GL. *Surgical Treatment of Congenital Heart Disease*. Philadelphia, PA: Lea & Febiger, 1966.)

Systemic-Pulmonary Anastomosis

Infants with TGA/VSD and severe LVOTO have been successfully palliated with systemic-pulmonary anastomosis. Statistics are limited but presently operative mortality with a Gore-Tex interposition shunt may be as low as 5%. The higher risk for developing pulmonary vascular obstructive disease in patients with TGA makes continuing reassessment of pulmonary vascular resistance imperative during follow-up.

CORRECTIVE SURGERY

Although medical management and interventional procedures play an important role in the initial care of the neonate with TGA, this anomaly remains a surgical disease; initial medical management is geared toward making the infant as good a candidate as possible for surgical correction. Numerous surgical options have been available to the infant with various variations of TGA (Table 49.3), although the arterial switch (\pm additional procedures as necessary) is currently the procedure of choice for most of these patients.

Surgery for TGA/IVS or TGA/VSD without Associated Outflow Tract Obstruction

Physiologic Correction (Atrial Switch)

Physiologic correction of TGA became a reality with the atrial switch procedures described by Senning (53) and by Mustard (54). In the Senning repair (Fig. 49.27), the atrial baffle is fashioned in situ using tissue from the right atrial wall and interatrial septum, whereas in the Mustard operation (Fig. 49.28), after resection of most of the atrial septum, the baffle is made from autologous pericardial tissue or (rarely) synthetic material. In terms of connections, the atrial switch repair imposes a discordant AV connection on the existing discordant AV connections; this “double-negative” results in a “normal” (i.e., series) circulation (Fig. 49.29).

The optimum timing for atrial switch repair has also become a historical footnote in the arterial switch era. In contrast to the arterial switch, atrial switch operations may be delayed for a few weeks to several months after birth (and BAS). The intervals between diagnosis, palliative BAS, and surgery may result in additional mortality and morbidity; in a current era multi-institutional report (55), 4% of uncorrected patients with simple TGA died by 30 days of age despite what was considered an adequate BAS. In the atrial switch era, the choice between the Senning and Mustard operations was controversial. Proponents of the Senning repair advanced that the operation was easier to perform, used minimal (if any) prosthetic material or nonviable tissue, had less compromised atrial volumes and compliances, and was followed with a lower frequency of systemic venous obstruction and “late” dysrhythmia. Others demonstrated that modifications to the Mustard procedure resulted in reduced early mortality, reduced systemic and pulmonary venous obstructions, and less dysrhythmia. Superiority of either surgical technique outside of individual experience has not been convincingly established.

Results and Sequelae of Physiologic Correction

Using cardiopulmonary bypass with profound hypothermia (with or without circulatory arrest), these operations were routinely applied to neonates and infants often with a remarkably low early operative mortality through the early 1990s (56). Combined data more broadly representative of current results suggest 10-year survival rates of 85% to 90% (56,57).

In patients with TGA/VSD, atrial repair may be more complicated, early and late postoperative mortality is higher, and postoperative complications are more frequent than for TGA/IVS. A literature review (9) concerned with 234 patients operated on mostly in the 1970 decade indicated an average early mortality of 23%; other reported hospital mortality rates ranged from 10% to 60%, and long-term survival rates remain disappointing, with 5-year survival estimates about 60% to 70%. The problems encountered with this subgroup most likely reflect the increased coexistence of adverse morphologic (associated anomalies) and physiologic (pulmonary hypertension and vascular disease) factors.

TABLE 49.3 Surgical Options Available to the Infant with Transposition of the Great Arteries

Anatomy	Surgical Options	Comments
TGA/IVS	Physiologic repair Senning or Mustard	Usually elective, neonatal–1 y
	Anatomic repair (primary) Arterial switch (Jatene)	Neonatal period, usually within 2 wk of age
TGA/IVS with “prolonged” low LV pressure	Physiologic repair Senning or Mustard	Usually elective, 1 mo–1 y
	Anatomic repair (delayed) Two-stage arterial switch	Long “preparation” period “Rapid two-stage switch”
TGA/VSD	Physiologic repair Senning or Mustard with VSD closure	Poor long-term results
	Anatomic repair Arterial switch with VSD closure	Usually neonatal repair; PAB occasionally (multiple VSDs)
	Interventricular baffle repair	Not all VSDs suitable
	Damus-Kaye-Stansel: VSD closure (LV→PA); proximal PA to Ao anastomosis; RV to distal PA conduit	Used when coronary translocation impossible aortic valve closure
TGA/VSD/PS	VSD closure (LV→Ao), RV to PA conduit (Rastelli)	Palliative systemic-to-pulmonary shunt frequently performed
		Conduit replacement frequently necessary
	VSD closure (LV→Ao), anterior translo- cation of PA with direct connection to RV–“REV” procedure (LeCompte)	Long-term pulmonary regurgitation
TGA/PVOD	Physiologic repair, palliative	Symptomatic improvement
	Anatomic repair, palliative	

Ao, aorta; IVS, interventricular septum; LV, left ventricle; PA, pulmonary artery; PAB, premature atrial beats; PS, pulmonary stenosis; PVOD, peripheral vascular occlusive disease; REV, Réparation à l'étage ventriculaire; RV, right ventricle; TGA, transposition of the great arteries; VSD, ventricular septal defect.

Persistent and frequently progressive functional cardiac abnormalities have long been recognized following physiologic repair and include (a) residual intra-atrial shunts, (b) caval and pulmonary venous obstructions, (c) right ventricular dysfunction, (d) tricuspid valve insufficiency, and (e) arrhythmia. More recent series of either the Mustard or Senning repairs report a significantly reduced incidence of baffle leaks or venous obstruction, but right ventricular dysfunction to some extent and dysrhythmias in particular remain important late concerns.

Residual intra-atrial baffle shunts occur most commonly at the superior right atrial-baffle suture line, may cause either systemic-to-pulmonary or pulmonary-to-systemic venous shunting, and are readily detected by color Doppler echocardiography. In the absence of major coexistent systemic venous obstruction, there is usually little or no arterial oxygen desaturation, and a net left-to-right shunt takes place. Although trivial leaks have been observed at late postoperative angiography in 10% to 20% of patients, significant leaks requiring reoperation have been uncommon (1% to 2%).

Systemic and pulmonary venous pathway obstructions are potentially serious complications. The neonate has been considered at greater risk for both types of venous obstruction because of the limited anatomic spaces involved. The causes of obstruction that have been implicated include (a) improper baffle geometry and suture line placement, (b) contraction of the pericardial or synthetic material baffle, and (c) scar tissue or adhesions involving the baffle and excised margins of the atrial septum.

Superior vena caval pathway obstruction appears postoperatively in about 5% to 10% of patients with a Mustard type repair (Fig. 49.30). Severe obstruction may present early after surgery with clinical signs of upper extremity plethora or chylothorax, and long-standing obstruction may lead to hydrocephalus. Even anatomically severe obstruction may remain asymptomatic, however, because of decompression of the superior vena cava by the azygous or hemiazygos system. Because obstruction can be present without signs or symptoms, a more appropriate frequency (about 17%, in Mustard series; about 14%, in Senning series) may be reflected by considering only patients who had late postoperative catheterization examination. The usual location of the obstruction is distal to the superior vena caval entrance, within the systemic venous atrium at the site of excision of the superior remnant of the atrial septum (Fig. 49.30). In addition to surgical revision, balloon catheter dilation, stent placement, and an innominate vein to left (physiologic right) atrial appendage shunt all have been used successfully to achieve temporary relief for both acute and chronic superior vena cava obstruction.

Inferior vena caval obstruction is a serious but infrequent (about 1%) complication of atrial switch repair. The low occurrence may reflect a technical modification (Figs. 49.31 and 49.32) that involves incising the free (atrial) wall of the coronary sinus, which enlarges the sinus opening into the systemic venous chamber and widens the area that serves as the inferior vena caval entrance to this chamber.

Figure 49.27. Atrial switch operation (Senning technique). Operation is performed using cardiopulmonary bypass with cold cardioplegic myocardial protection or during profound hypothermia with total circulatory arrest. **A:** A right atriotomy is made in front of and parallel to the caval veins and extended into the atrial appendage. This exposes the atrial septum (with its balloon septostomy defect). The atrial septum is now incised anteriorly, superiorly, and inferiorly to form a septal flap (shaded area) as large as possible, which remains fixed posteriorly between the caval entrances. The wall between the coronary sinus (CS) and the left atrium may be incised to provide a large posterior lip for the inferior septal flap suture line (see B) and direct coronary sinus return to the newly formed systemic venous return chamber. **B:** The systemic venous chamber and conduit to the mitral valve is formed posteriorly by the repositioned septal flap (shaded area), and the conduit then is completed anteriorly by suturing the posterior right atrial free wall flap (z z z) anteriorly to the anterior septal limb (z z z) as in (C). A left atriotomy is made as long as possible in the internal atrial groove (exposing the orifices of the right pulmonary veins). **C,D:** The pulmonary venous chamber and pathway to the tricuspid valve are completed with the suturing of the anterior right free wall atrial flap (asterisk) over the right pulmonary veins to the anterior lip of the left atriotomy (asterisk). **D:** Black arrows indicate systemic venous caval flow through the newly created atrial tissue conduit and systemic venous chamber (cross-hatched area) toward the mitral valve. White arrow indicates pulmonary venous flow path in pulmonary venous atrium passing behind, rightward, and anterior to the systemic venous chamber behind the tricuspid valve (TV). BAS, balloon atrial septostomy; IVC and SVC, inferior and superior vena cavae; MV, mitral valve; PV, PVL, and PVR pulmonary veins, left and right.

Pulmonary venous obstruction, which may be evident immediately after surgery or become prominent a few weeks or months later, is a less common but more lethal type of obstruction than the systemic venous type. A low frequency (about 2%) of pulmonary venous obstruction has been reported for both the Mustard and Senning types of atrial repair in two series representing the original surgical development teams. Prompt suspicion should be aroused by a postoperative chest roentgenogram with pulmonary venous congestion or unexplained arterial desaturation in the postoperative period. The diagnosis usually can be made by echocardiography. At cardiac catheterization or Doppler echocardiography, a significant mean pressure difference is obtained between the posterior and anterior segments (Fig. 49.31) of the new pulmonary venous atrium. Reoperation with atrial baffle revision should be considered for hemodynamically severe obstructive complications of the atrial switch repair.

Tricuspid valve regurgitation has been recognized postoperatively, but hemodynamically important tricuspid regurgitation (TR) is rare (1% to 2%) in most series concerned with

TGA/IVS. In contrast, moderate and severe TR is more prevalent (about 5% to 10%) in patients with TGA/VSD. Manipulation and damage to the tricuspid valve and its support apparatus, as well the occurrence of a right bundle-branch-block pattern during repair of the defect, are considered responsible for the TR. Surgery for important TR, including annuloplasty and prosthetic valve replacement, has been disappointing in the long term.

The depressed right ventricular function that has been reported in many studies is in sharp contrast to the normal daily activities and the absence of clinical symptoms in most postoperative children (58,59). Most intermediate (5- to 15-year) postoperative assessments report significantly abnormal resting and exercise responses for right ventricular ejection fraction (decreased) and abnormal resting measurements for right ventricular volumes (increased) in most patients (59,60). The progressive increase in right ventricular volume also may be due to increased flow from persistently enlarged bronchial arteries, producing a "silent" volume overload to the systemic ventricle (Fig. 49.16B).

Figure 49.28. Atrial switch operation (Mustard technique). **A:** After establishing cardiopulmonary bypass or profoundly hypothermic total circulatory arrest, the right atrium is opened through an oblique atriotomy incision, exposing the interatrial septum (IAS) with its BAS defect. **B:** The atrial septal remnants are excised widely posteriorly, inferiorly, and superiorly but not anteriorly to preserve a small anterosuperior rim of atrial septal tissue between the superior vena cava and tricuspid valve (TV). In all atrial switch operative techniques, the area of the sinus node and the sinus node artery must be scrupulously avoided in an effort to minimize dysrhythmia complications. As often done in the Senning operation (Fig. 49.27), the free margin of coronary sinus (CS) may be divided downward for several millimeters, a maneuver that transfers the coronary sinus opening into the future systemic venous chamber and also widens the area that becomes the extension of the inferior vena cava into this chamber. **C:** An appropriate baffle material, usually pericardium (*cross-hatched area*) is sutured in place. Suturing starts across the floor of the left atrium along a line immediately to the left of the left pulmonary vein orifices. The suturing continues around the orifices of the superior and inferior vena cavae (SVC, IVC) and finally along the anterior atrial septum resection line to complete the baffle conduit. **D:** The oblique atriotomy is closed. *Black arrows* indicate systemic vena caval flow patch through the newly fashioned pericardial (or synthetic material) conduit and systemic venous chamber (*cross-hatched area*) toward the mitral valve (MV); *white arrow* indicates pulmonary venous flow path in pulmonary venous atrium passing behind, rightward, and anterior to the systemic venous chamber toward the tricuspid valve (TV). PV, pulmonary valve.

Formal exercise performance testing demonstrated decreased endurance indices in intermediate and late postoperative studies (61–65). Post-Mustard repair patients perform significantly less work and have lower peak heart rate and peak minute oxygen consumption than controls. They also manifest an abnormal increased ventilatory response to exercise. Exercise performance in this patient population is uniformly diminished, which appears to be a consequence of both decreased heart rate and stroke volume response.

At least 10% of operative survivors have important depression of right ventricular function and about 90% are in New York Heart Association functional Class I. Severe, symptomatic right ventricular failure is an infrequent but major complication (66). It may be associated with progressive TR and is observed more often in the VSD repair subgroup. In severely symptomatic patients, heart transplantation has been used as a treatment option, as has “conversion” to anatomic correction (66–70) (see section on “Surgery for Right Ventricular Failure Following Physiologic Correction”).

Postnatally, the morphologic right ventricle may be incapable of functioning normally as a systemic ventricle, despite the fact that prenatally the right ventricle and tricuspid valve sustain systemic pressures as well as larger blood flow volumes than the left ventricle and mitral valve. The following

explanations for postnatal and postatrial repair subnormal right (systemic) ventricular function remain speculative:

1. Right ventricular myocardial fiber arrangements may not be optimum for systemic function, and there may be a mismatch between right ventricular coronary blood supply and systemic ventricular work demand. In this regard, the anatomic structure of the ventricular free walls is dissimilar; the left ventricular free wall is composed predominantly of stratum compactum (coronary-supplied myocardium), whereas the right ventricular free wall consists predominantly of stratum spongiosum (trabeculae carneae).
2. The right ventricle can achieve only suboptimal pumping function because the transposed ventricular pressure relationships force the ventricular septum to bulge posterior–leftward and to present a concave septal surface during contraction. Furthermore, the tricuspid valve is supported by relatively small papillary muscles in comparison to the mitral valve and this, in conjunction with the abnormal concave right ventricular septal surface, may result in TR.
3. The right ventricle is functionally diminished as a systemic ventricle compared with the left ventricle because it contains a hypokinetic segment (i.e., the infundibulum).

Figure 49.29. Angiocardiograms showing systemic and pulmonary venous atrial morphology following intra-atrial baffle repair (Mustard) operation. Frontal (A) and lateral (B) views of the systemic veins (superior [SVC] and inferior vena cava [IVC]), new systemic venous atrium (SVA), left ventricle (LV), and pulmonary artery (PA). Note the adequate conduit diameters and the absence of constriction in the superior and inferior limbs of the systemic venous atrium. LAA and RAA, left and right atrial appendages. Frontal (C) and lateral (D) views of the new pulmonary venous atrium (PVA). This chamber consists of a posterior segment (PVA_p) receiving the pulmonary veins and an anterior segment (PVA_a) that formerly was a portion of the original right atrium. The PVA_a empties via the tricuspid valve (TV) into the right ventricle (RV) and aorta (AO).

4. Prerepair hypoxemic coronary perfusion may cause sufficient myocardial fibrosis and functional damage to preclude normal systemic right ventricular function, but normal pulmonary right ventricular function usually returns after late second-stage arterial switch repair.

Speculations aside, the accumulating short-term and mid-term postarterial switch repair findings of normal left ventricular systemic function support the basic premise that the left ventricle and mitral valve are better suited for this function.

After atrial repair procedures, several other functional abnormalities persist as a consequence of the continuing anatomic transposition: abnormal function of the mitral valve-LVOT subunit (characterized by abnormal systolic movement and coarse diastolic flutter of the anterior mitral valve leaflet, systolic bulging of the basal segment of the ventricular septum into the outflow tract, and systolic pressure differences across the outflow tract) and abnormal distribution of pulmonary blood flow to the right lung and hypoplastic changes in the left pulmonary vascular bed. The infrequent late occurrence

of pulmonary vascular obstructive disease, new or progressive, has been observed postoperatively, even in patients with TGA/IVS.

Postoperative dysrhythmias after atrial switch procedures are commonly encountered during long-term follow-up studies. Indeed, the prevalence of atrial electrophysiologic disturbances in these patients constituted one of the major arguments for the arterial switch repair. The reported loss of sinus rhythm and the occurrence of dysrhythmias range widely, from 13% to 100% (8,56,57,71–74). This disparity primarily reflects differences in the definition of dysrhythmia, the type and extent of follow-up study (routine ECG, 24-hour ambulatory monitoring, exercise ECG monitoring, electrophysiologic testing), and, importantly, the interval since surgery. The pattern of progressive loss of normal sinus rhythm and increase in atrial rhythm disturbances over years is particularly well documented following the Mustard-type repair but also is widely observed after the Senning-type repair. There appears to be a gradual time-related decrease in normal sinus rhythm: In one series concerned with the Mustard repair of TGA (without

Figure 49.30. Frontal angiogram of systemic venous pathways following atrial repair. Note the dilated superior vena cava (SVC); a 5 mm Hg mean gradient was detected on catheter pullback. IVS, inferior vena cava; SVA, systemic venous atrium.

Figure 49.31. Two-dimensional echocardiogram (subcostal view) in 8-year-old with TGA/IVS with Mustard repair at 1 year of age. Note reconstructed pulmonary venous atrium (PVA) compartmentalized into posterior segment (PVA_p) with left pulmonary venous drainage and anterior segment (PVA_a) with tricuspid valve. Note wide unobstructed isthmus (i) between PVA_p and PVA_a, and pericardial baffle separating PVA from systemic venous atrium (SVA). TV, tricuspid valve.

significant VSD), the probability of being in sinus rhythm at 1 year was 72%, at 5 years 56%, at 10 years 50%, and at 13 years 43%.

The predominant dysrhythmias include marked sinus bradycardia, ectopic atrial rhythm, slow junctional rhythm, and supraventricular tachycardia, especially atrial flutter. AV conduction disturbances, surgical complete heart block, and premature ventricular beats have been noted as well (Table 49.4). The most prevalent basic mechanisms observed are sinus bradycardia and intermittent or fixed slow junctional rhythms. Not only is bradycardia present at rest, but peak heart rate response to exercise is blunted as well. Episodes of atrial tachycardia or atrial flutter are not infrequent, occurring in about 5% to 15% of long-term survivors. The terms bradycardia-tachycardia syndrome and sick-sinus syndrome have been applied descriptively when patients manifest periods of marked bradycardia, sinoatrial arrest, or block with AV junctional escape and slow junctional rhythms, as well as the episodes of tachycardia. Risk factors for these rhythm and conduction disturbances are not known to be different for the Mustard and Senning atrial switch procedures.

The origin of the various dysrhythmias may be intraoperative damage to the sinus node or sinus artery, interruption of intra-atrial conduction by damage to internodal pathways, or intraoperative damage to AV node conduction tissue. Histologic examination of the sinus node region revealed that the sinus node, sinus node artery, and paranodal tissues are frequently abnormal. Acute changes include suture compression, necrosis, or infarction of the sinus node itself with perinodal hemorrhage and edema; chronic changes include marked nodal and paranodal fibrosis. Although it is no longer contended that atrial conduction occurs through discrete, well-defined atrial intranodal tracts, the various extensive surgical incisions, and suture lines in atrial switch procedures result in marked delays in intra-atrial conduction throughout the atria. These local areas of conduction delay are significant in providing the substrate for the development of intra-atrial reentry types of tachycardia, and late postoperative electrophysiologic studies indicate a high frequency of inducible sustained atrial flutter. Despite changes in surgical technique, including special care to avoid direct surgical damage to the sinus node and its artery, and perhaps also efforts at preserving the anterior portion of the atrial septal limbus for intranodal conduction, a high frequency of late arrhythmia persists in essentially all atrial repair series.

Symptoms of palpitations, dizziness, or syncope may result during either tachycardia or bradycardia events; consequently, ECG documentation in symptomatic patients is critical. Patients with atrial tachycardia may be unaware of its occurrence if the ventricular rate is the result of 2:1 or 3:1 AV conduction. During exercise or excitement, however, 1:1 conduction may occur and result in abrupt onset of palpitations, dizziness, or syncope as a result of the rapid ventricular rate. Some patients may not experience an abrupt onset but rather may develop symptoms of tachycardia-induced heart failure over weeks or months.

Antiarrhythmic control in these patients may be quite difficult because bradycardia and tachycardia often occur concurrently, and pharmacologic therapy for the tachycardia may severely further depress pacemaker function and thus aggravate bradycardia. Permanent implanted pacing has been recommended by some in this situation, and also for isolated symptomatic bradycardia, including heart rates <30 beats per minute, Stokes-Adams episodes, and poor ventricular function with bradycardia, especially when associated with major ventricular ectopic activity. Although clearly indicated for the management of some patients, neither ant arrhythmic medication nor standard pacemaker implantation has been conclusively shown to affect the frequency of sudden death. The recent successful use of episodic transvenous and transesophageal

Figure 49.32. Surgical technique of the arterial switch operation. **A:** Aortic cannula is positioned distally in the ascending aorta, the ductus arteriosus is divided between suture ligatures, and the branch pulmonary arteries are dissected out to the hilum to provide adequate mobility for anterior translocation. The broken lines represent the levels of transection of the aorta and the main pulmonary artery. Marking sutures are placed in the anticipated sites of coronary transfer. **B:** Transection of the great arteries. The LVOT, neo-aortic valve, and coronary arteries are thoroughly inspected. **C:** The coronary arterial buttons are excised from the free edge of the aorta to the base of the sinus of Valsalva. **D:** The coronary buttons are anastomosed to V-shaped excisions made in the neo-aorta.

pacing for tachycardia cardioversion and the development of implantable devices for pacing-induced cardioversion offer the potential for both treating tachycardia and preventing bradycardia with backup demand pacing.

Late, sudden, unexplained death has been reported with a frequency of 2% to 10% (75,76). The presence of either sinus node dysfunction or rapid atrial dysrhythmias, alone or in combination (as is frequently observed), could result in sudden death. Although these rare events are possibly bradyarrhythmic in origin, the recent recognition of a higher-than-expected frequency of intramural coronary arteries in TGA (4,77) may play

a role as well. Many cases of late sudden death occur during exercise or increased activity, during which time bradyarrhythmias would be less likely; impaired coronary flow resulting from compression of the transmural segment of the (usually left) coronary artery may in fact be the precipitating cause.

“Anatomic Correction” (Arterial Switch)

Although the Mustard and Senning atrial switch procedures achieved widespread acceptance and success during the past four

Figure 49.32. (Continued) E: The pulmonary artery is brought anterior to the aorta (LeCompte maneuver). Anastomosis of the proximal neo-aorta is shown. F: The coronary donor sites are filled with autologous pericardial patches. A single U-shaped patch (F) or two separate patches (G) may be used. H: Anastomosis of the proximal neopulmonary artery and the distal pulmonary artery. (Modified from Castañeda AR. Anatomic correction of transposition of the great arteries at the arterial level. In: Sabiston DC Jr, Spencer FC, eds. *Surgery of the Chest*. Philadelphia, PA: WB Saunders, 1990:1435–1446.)

decades, the search for an operation to return the great arteries to their normal ventricular connections continued. This search was stimulated primarily by the accumulating observations at mid- to late-term follow-up studies of (a) an increasing frequency of important dysrhythmic complications, including sudden, unexplained death; (b) the threat of late right ventricular dysfunction and major TR in a ventricle most likely unsuited for a lifetime of systemic function; and (c) dissatisfaction with the operative mortality and results in the subgroup of infants with TGA and large VSD. Starting in 1954, numerous innovative procedures to achieve an anatomic correction were described, but clinical success was not achieved until 1975 by Jatene et al. (78).

In the 35+ years since the introduction of the arterial switch operation by Jatene and colleagues in 1975, arterial level repair has replaced atrial level repair as the surgical procedure of choice for both simple and complex forms of TGA. Although frequently referred to as “anatomic” correction, in reality, there are important differences in the postoperative patient compared with the structurally normal heart. The anatomic pulmonary valve must serve in the systemic circulation lifelong, and there are accumulating data on progressive neo-aortic valve dysfunction and root dilation during the second and third decades of follow-up. In addition, as opposed to the normal heart, following the LeCompte maneuver both pulmonary arteries are ante-

rior to the ascending aorta; posterior tension can cause further distortion of the neo-aortic root and/or cause supra-valvar pulmonary stenosis. In patients without significant comorbidities or major coexisting cardiac defects (e.g., dextrocardia, aortic arch obstruction), surgical mortality can be expected to be <5%.

The anatomic challenges of arterial switching have been met by the application of novel surgical techniques. In brief (Fig. 49.32), the great arteries are transected in a manner that allows eventual reanastomosis of the distal aortic segment to the proximal pulmonary artery (neo-aortic root). Transfer of the coronary arteries to this pulmonary segment is facilitated by their excision from the aortic sinus with a cuff of adjacent aortic wall. The proximal aortic segment (neopulmonary root) may be connected to the distal pulmonary artery segment by an end-to-end anastomosis using LeCompte and associates' innovative maneuver, which passes the anterior aorta posterior to the bifurcation of the pulmonary artery (Fig. 49.33). Alternatively, the pulmonary artery connections can be established by using an interposed prosthetic tubular conduit or direct connection.

A critical physiologic challenge to anatomic repair concerns the functional adequacy of the left ventricle, which preoperatively faces the pulmonary circulation and postoperatively must instantly cope with the systemic workload. In the current era of increasing numbers of babies detected before or shortly after birth, an "unprepared" left ventricle is increasingly uncommon. Adequate left ventricular muscle mass for successful systemic function is usually present in early infancy in patients with TGA/IVS (see also section on "Surgery for TGA with Low Left Ventricular Pressure"), but may also be present in older patients with TGA and associated anatomic abnormalities that cause a continued increased afterload to the left ventricle (Fig. 49.34). These associated anomalies include (a) a nonrestrictive PDA, (b) surgically remediable or "dynamic" left ventricular outflow obstruction, (c) a delayed decrease in pulmonary vascular resistance and persistent pulmonary hypertension, or (d) a large, nonrestrictive VSD.

Indeed, the initial clinical success with surgical arterial switch and the first confirming reports approximately three

Figure 49.33. Angiocardiograms (lateral and oblique views) showing great artery relationships before and after arterial switch with LeCompte maneuver (79) for TGA. **A:** Lateral view of a right ventriculogram shows discordant ventriculoarterial connections and large PDA (prostaglandin E_1 infusion). **B,C:** Postoperative (2 years) right and left ventriculograms showing concordant ventriculoarterial connections, and (B) widely open reconstructed pulmonary artery root with minimal stretching and narrowing of confluence of pulmonary artery branches (arrow) as they pass anterior to ascending aorta. In (C), note the dilated neo-aortic root and some slight posterior displacement (arrow) of ascending aorta. Pressures were RV, 34/5; MPA, 36/12; LPA, 34/12; LV, 90/7; AO_a , 90/50 mm Hg. Left and right ventricular ejection fractions were 99% and 112% of normal, respectively. AO_a and AO_d , ascending and descending aorta; LV, left ventricle; MPA, main pulmonary artery; RV, right ventricle.

(Arterial switch repair data derived from Kirklin JW, Blackstone EH, Tchervenkov CI, et al.; Congenital Heart Surgeons Society. Clinical outcomes after the arterial switch operation for transposition: patient, support, procedural and institutional risk factors. *Circulation* 1992;86:1501–1515; Mustard repair data derived from Trusler GA, Williams WG, Duncan KF, et al. Results with the Mustard operation in simple transposition of the great arteries 1963–1985. *Ann Surg* 1987;206:251–260.)

decades ago concerned only infants with TGA/VSD without major pulmonary vascular disease. The use of arterial switch for patients with TGA/VSD as well as the Taussig-Bing anomaly is now widely regarded as the surgical procedure of choice, both with regard to operative mortality and intermediate-term results.

Definitive early (neonatal) one-stage arterial repair is presently preferable to early palliation with pulmonary artery banding and later arterial switch surgery. In an ongoing multi-institutional study (see later), older age at surgery was determined to be an incremental risk factor for death (55) and increasing neurologic morbidity was seen with older age at repair in the Boston Circulatory Arrest Study (35,36,79). In patients with TGA/large VSD who undergo palliative pulmonary artery banding, improper adjustment of the band may cause either persistent pulmonary hypertension with possible pulmonary vascular disease or unacceptable hypoxemia. Banding too close to the pulmonary valve may distort and damage the pulmonary (neo-aortic) valve and has been related to a higher frequency of neo-aortic valvar insufficiency than that observed after primary one-stage arterial repair.

The concept that the neonatal left ventricle in TGA/IVS would successfully sustain the systemic circulation after arterial switch repair, if accomplished in the first few weeks of life (or longer), has been validated. Although most early and midterm follow-up studies concerned with systemic ventricular function in the arterial repair patient have established the functional advantages of arterial over atrial switch repair (80,81), past experience with other complex surgical procedures urges caution about final pronouncements because the potential for later problems clearly exists (82).

Results and Sequelae of the Arterial Switch Operation

Early, risk-unadjusted mortality rates are <10% in most recent reports (31,83–87). Several anatomic, technical, and institutional risk factors for increased mortality have been reported. Anatomic variants that may impact operative mortality include (a) an intramural course of a coronary artery, (b) a retropulmonary course of the left coronary artery, (c) multiple VSDs, (d) coexisting abnormalities of the aortic arch, (e) straddling AV valves, and (f) prior pulmonary artery banding. It appears that with increased surgical experience these effects may be minimized. Longer duration of global myocardial ischemic (cross-clamp) and prolonged circulatory arrest times are risk factors for operative mortality and prolonged hospital length of stay, as is the number of procedures done at a given institution (55,88–90).

Early mortality usually is related to kinking or obstruction of the coronary arteries during transfer to the neo-aorta, an “unprepared” left ventricle, or hemorrhage from the multiple suture lines. Late mortality has been reported with an incidence of 1% to 2% (with a shorter follow-up duration than for physiologic correction), usually as a result of myocardial ischemia or pulmonary vascular obstructive disease or during reoperation for supraventricular obstruction.

Supraventricular pulmonary stenosis is widely recognized as the most frequent short-term complication of arterial level repair (91,31). The need for reintervention for supraventricular pulmonary stenosis ranges between 5% and 30%; most institutions report a decreasing incidence of this complication with increasing experience with the operation. Postoperative obstruction may occur at multiple levels following anatomic correction:

1. Diffuse hypoplasia of the main pulmonary artery may result from inadequate mobilization of the branch pulmonary arteries causing tension on the anastomosis. With somatic growth, there may be inadequate growth of the main pulmonary artery resulting in “flattening” of the reconstructed right ventricular outflow tract in the anterior–posterior direction (Fig. 49.35A,B).
2. Circumferential narrowing at the suture line may occur and cause a more discrete type of supraventricular narrowing (Fig. 49.35C,D).
3. Branch pulmonary artery stenosis (usually left) is more common in cases of more side-by-side great arteries when the LeCompte maneuver is used. In these cases, the left pulmonary artery may “bowstring” over the reconstructed neo-aorta, causing significant hypoplasia of the left pulmonary artery (Fig. 49.35E,F).
4. Finally, multiple levels of obstruction may occur in combination.

Treatment for supraventricular pulmonary stenosis includes both reoperation and balloon angioplasty and is generally indicated when right ventricular pressure approaches or exceeds systemic levels. Surgical relief of supraventricular pulmonary stenosis usually requires patch angioplasty; the patch may need to extend through the neopulmonary annulus into the infundibulum. In these cases, it is critical that the course of the right coronary artery is properly identified preoperatively because the right coronary may be difficult to identify during surgery due to dense adhesions. If the right coronary artery has an anterior course to reach the right AV groove (“inverted” right or single left coronary pattern) (see also the section on Morphology), transannular patching is contraindicated and a conduit may be necessary. Balloon angioplasty has only rarely been successful. The discrete branch pulmonary artery stenoses or circumferential stenoses in the main pulmonary artery (Fig. 49.35D) are the types most likely to be successfully relieved with balloon angioplasty.

Figure 49.35. Anteroposterior (A) and lateral (B) angiographic frames of a patient with severe supravulvar pulmonary stenosis causing systemic right ventricular pressure. Note anterior–posterior narrowing (*straight arrows*) and moderate peripheral narrowing (*curved arrows*). This type of narrowing is due to tension on the pulmonary anastomosis caused by inadequate dissection of the branch pulmonary arteries. Anteroposterior (C) and lateral (D) angiographic frames of a patient with supravulvar pulmonary stenosis due to circumferential narrowing at the anastomosis (*arrows*). Right ventricular pressure was 110% systemic. Anteroposterior (*continued*)

Supravulvar aortic stenosis (see Fig. 49.35F) is significantly less common than supravulvar pulmonary stenosis. Peak systolic ejection gradients across the aortic anastomosis of >20 mm Hg are extremely uncommon, being present in fewer than 5% of patients, with reoperation necessary in <2% of patients. After the LeCompte maneuver, the anterior

aspect of the ascending aorta often manifests some posterior displacement caused by the stretched anterior-placed pulmonary trunk and bifurcation (Figs. 49.35F and 49.36). A rarely experienced pathologic expression of this posterior displacement, obstructive kinking of the proximal transverse aortic arch (Fig. 49.36), has been reported after the arterial

Figure 49.35. (Continued) (E) angiogram in the main pulmonary artery showing severe stenosis and hypoplasia of the left pulmonary artery. This patient had TGA/IVS with side-by-side great arteries; following the LeCompte maneuver, the left pulmonary artery draped over the aortic anastomosis causing, in addition, moderate supravalvular aortic stenosis (F) (with a peak systolic ejection gradient from left ventricle to aorta of 30 mm Hg). A lung perfusion scan demonstrated that 95% of the pulmonary blood flow entered the right lung. Following balloon angioplasty, the diameter of the left pulmonary artery increased by 200%, and the left lung flow increased to 22% by follow-up lung scan. (Parts A–D from Wernovsky G, Hougen TJ, Walsh EP, et al. Midterm results after the arterial switch operation for transposition of the great arteries with intact ventricular septum: clinical, hemodynamic, echocardiographic and electrophysiologic data. *Circulation* 1988;77:1333–1344, with permission.)

Figure 49.36. Aortograms in a patient with DORV, anterior malalignment subpulmonary VSD (with previous coarctation repair) illustrating new obstructive kinking in the proximal aortic arch following to arterial switch with LeCompte maneuver. **A:** At 10 months of age before arterial switch, note the well-repaired distal arch (c); only a 5-mm Hg gradient was registered across the moderately hypoplastic transverse aortic arch (AO_t). **B:** At 2 years of age, 1 year after the arterial switch, note that the anterior positioning of the pulmonary artery trunk (white curved arrow) has caused posterior displacement, kinking, and acute angulation (black arrow) where the transverse aortic arch joins the ascending aorta (AO_a). A 30-mm Hg systolic gradient was present. AO_d.

switch using the LeCompte maneuver. This significant “neocoarctation” has only been reported in patients with TGA associated with a prior coarctation repair (with associated tubular hypoplasia of the transverse arch) and may reflect either inherent anatomic abnormalities of the arch or inadequate surgical technique rather than the LeCompte maneuver per se.

The status of the neo-aortic (anatomic pulmonary) root and valve remains a subject of long-term concern (82). At the time of neonatal correction, the native pulmonary root is frequently larger than the ascending aorta, especially in TGA/VSD. Despite the “tailoring” that is frequently necessary to accommodate this size “mismatch,” the aortic anastomosis is not under much tension, and adequate circumferential growth of the suture line, commensurate with somatic growth, is characteristic (31). Multiple follow-up studies have described an enlarged neo-aortic root (Fig. 49.37) and annulus (Fig. 49.38) following both neonatal and two-stage anatomic correction (92–95).

The “Achilles’ Heel” of the Arterial Switch Operation: The Neo-aortic Root, Valve, and Translocated Coronary Arteries

Now that there are increasing numbers of patients with TGA surviving into their fourth decade of life following the arterial switch operation where they are at increasing risk for atherosclerosis, hypertension, obesity, diabetes, etc., there is growing concern about the long-term (“life-long”) fate of the anatomic pulmonary (“neo-aortic”) valve in the systemic circulation and the function and long-term health of coronary arteries that underwent removal and translocation in the first few weeks of life. There remain many unknowns: does the

heart eventually reinnervate decades after the great vessels are transected, “switched,” and reanastomosed? Can an arterial switch survivor feel angina if he or she has ischemia?; Will there be accelerated coronary disease—or “different” coronary disease—in this population? and What is decades-long likelihood that the anatomic pulmonary valve will remain competent?

First and foremost, increasingly prevalent in the literature are reports of inappropriately progressive dilation of the neo-aortic root following anatomic correction. There appears to be enlargement out of proportion to somatic growth in most reports (92,94–96). The data from Marino et al. (92) suggests that neo-aortic root dilation is progressive, and finding not replicated with the report from Schwartz et al. (94). Of some concern is the earlier appearance of significant root dilation in one recent report from Boston (94). In one of the initial reports of neo-aortic root dilation (97), in 50 patients with serial echocardiographic measurements, there was (a) normal growth of the anastomosis, (b) stable growth of the dilated neo-aortic annulus, but (c) progressive dilation of the neo-aortic root (Figs. 49.37 and 49.38). This phenomenon is more likely to occur in patients with TGA/VSD, in whom the native pulmonary root is significantly larger than that seen in TGA/IVS. The etiology and long-term effects of progressive dilation of the neo-aortic root are unknown. Removal of the sinuses of valsalva with reimplantation of the coronary “buttons” and the supra-avalvular suture line may be causative factors of this progressive dilation.

There is a surprisingly high incidence of neo-aortic regurgitation following the arterial switch operation; however, in the overwhelming majority of cases, the degree of regurgitation is trivial to mild (92–95,98,99). There have been rare reports of more significant regurgitation, including isolated reports of

Figure 49.37. Echocardiographic images of the neo-aortic root and the aortic anastomosis at 2 weeks (left) and 6 1/2 years (right) after arterial switch. Note that the anastomosis is well seen at 2 weeks but is indistinguishable from the rest of the ascending aorta at 6 1/2 years. (From Hourihan M, Colan SD, Wernovsky G, et al. Growth of the aortic anastomosis, annulus and root after the arterial switch procedure performed in infancy. *Circulation* 1993;88:615–620, with permission.)

Figure 49.38. Postoperative measurements of the aortic anastomosis (A), the neo-aortic annulus (B) and the neo-aortic root (C) are plotted versus the square root of body surface area (BSA) in 50 patients following anatomic correction. The solid line and small dashed lines represent the mean and 95% confidence intervals, respectively. The large dashed line and shaded area represent the mean and 95% confidence intervals, respectively, for comparable structures in a control population ($n = 314$) of normal newborns, infants and children. IVS intact ventricular septum, PAB, pulmonary artery band, VSD, ventricular septal defect. (From Hourihan M, Colan SD, Wernovsky G, et al. Growth of the aortic anastomosis, annulus and root after the arterial switch procedure performed in infancy. *Circulation* 1993;88:615–620, with permission.)

aortic valve replacement (96). There is a higher incidence of neo-aortic root dilation and regurgitation following two-stage repair compared with primary repair. The highly variable incidence of neo-aortic regurgitation (from 0% to 50%) is most likely related to the methodology of investigation by which it is sought rather than due to technical modifications of the operation. Angiographic and auscultatory neo-aortic regurgitation is significantly less common than that reported in studies using color Doppler.

This high prevalence of neo-aortic regurgitation raises the important question of the adequacy of the anatomic pulmonary valve, normally with thin leaflets and little collagen and elastic tissue when present in the low-pressure pulmonary circulation to support the high-pressure systemic circulation over a patient's lifetime (97). Although trivial (color Doppler) regurgitation of a semilunar valve may be a normal finding, large studies using color Doppler in patients with normal hearts detect a high incidence of trivial to mild anatomic pulmonary valve regurgitation, but no aortic regurgitation is rarely detected using the same methodology. Before final pronouncements are made on the superiority of anatomic correction, long-term follow-up of the functioning of the neo-aortic valve and root must be obtained.

The long-term patency and growth of the coronary arteries are crucial for the arterial switch operation to be considered the procedure of choice for the surgical management of TGA. Patients with occlusion of the coronary arteries following anatomic correction may present with a spectrum of symptoms from cardiogenic shock to no symptoms at all (100–104). Intraoperative kinking or occlusion of a coronary artery usually results in acute ischemia and ventricular dysfunction, with inability to separate the patient from cardiopulmonary bypass. This problem must be suspected if the hemodynamics are poor, especially in association with arrhythmias or ECG changes, and may be confirmed with intraoperative echocardiography. The coronary anastomo-

ses should be inspected and revised if necessary; an internal mammary artery bypass may be necessary in extreme circumstances. Subacute kinking or occlusion may result in a chronic low-output state immediately after surgery. Although patients in this chronic low-output state eventually may leave the hospital, they are at risk for acute circulatory collapse weeks to months after the arterial switch operation. Late postoperative myocardial infarction and death have been reported in 1% to 2% of hospital survivors following the arterial switch. However, in one recent series, 13.5% underwent coronary revascularization at an average of 8 ± 4.3 years after surgery (105), and there are growing numbers or reports of coronary interventions in the second and third decades of life (106–109).

Although growth of the coronary anastomosis and continued patency are present in most patients at follow-up, asymptomatic occlusion of one of the coronary arteries may occur in as many as 1% to 2% of hospital survivors (103). Presumably, this type of occlusion takes place gradually, allowing adequate collateralization from the contralateral coronary system (Fig. 49.39). Myocardial perfusion studies following the arterial switch operation have shown a surprisingly high incidence of perfusion defects, the clinical significance of which are uncertain to date (110–113). Formal exercise testing has shown no evidence of ischemic changes in this group of patients (112,114).

Systemic (left) ventricular function has been preserved at early and midterm follow-up studies (80,115). Echocardiographic assessments in neonates and older infants indicate excellent preservation of both regional and global function, which suggests that permanent ischemic injury is uncommon. In the neonate, immediate post-repair left ventricular function has been noted to be impaired for the first few days after surgery, but subsequent predischarge assessments show almost uniformly normal systolic function, as do angiographic studies during follow-up. Left ventricular

Figure 49.39. Anterior (A) and lateral (B) projections of a selective injection in the left coronary system in a 2 ½-year-old child following neonatal anatomic correction. The coronary pattern was the “usual” variety for transposition; the left anterior descending (*single arrow*) and circumflex (*double arrows*) are well seen without distal stenoses. A prominent anterior right ventricular branch (*triple arrows*) is present. Selective right coronary injection (C) in an asymptomatic 15-month-old (also with “usual” coronary arteries for TGA) following neonatal anatomic correction. The proximal left coronary artery is completely occluded with collateralization from a markedly enlarged right coronary system. This child had a normal ECG; echocardiographic measurements of regional wall motion and left ventricular function (at rest) were normal, and cardiac index (3.4 L/min/m²) and left ventricular end-diastolic pressure (8 mm Hg) were normal at catheterization. (A and B courtesy of Dr. Henry Wiles, C courtesy of Dr. Daniel Diana.)

shape has been described as more globular following anatomic repair, end-diastolic volumes have been normal to only slightly enlarged, and ejection fraction and contractility have been normal. Follow-up of left ventricular function, particularly in patients following two-stage arterial repair, has shown some to have abnormal ventricular function, and end-diastolic and end-systolic volumes were slightly elevated (80).

Perhaps the most striking midterm advantage of anatomic correction over physiologic correction has been the low incidence of postoperative dysrhythmias (Table 49.4). Sinus rhythm has been present postoperatively with rare exceptions. Intracardiac electrophysiologic studies confirm normal sinus node function and normal AV conduction, with no evidence of ischemia-related ventricular ectopy on 24-hour ambulatory ECG monitoring (81,116).

In both surgical groups, there is a growing recognition of neurodevelopmental, social, and behavioral sequelae that may significantly impact on health-related quality of life

(117–119). Reports are mixed in this area, with some favoring the outcomes in the arterial switch patients, possibly related to improved cardiovascular health (65), while others suggest a similar patient-reported quality of life with either surgical technique that is similar to that in the general population (120). It has been shown that patients following the arterial switch operation get less physical exercise than the general US population, and have similar risk profiles to the rest of the United States for obesity, with one-third being either obese or at risk for obesity. In the most recent publication from the Boston Circulatory Arrest Study, patients at age 16 were four times more likely to be taking psychotropic medications compared to cardiovascular medications, and approximately two-thirds of that cohort received behavioral therapies and/or additional help at school. One-third had brain abnormalities detected on MRI (121). Multiple investigations confirm a higher-than-expected rate of attention deficit hyperactivity disorder, deficits in social cognition, theory of mind, and executive function (79,122).

TABLE 49.5 Postoperative Sequelae after the Mustard and Senning Operations

Postoperative Sequelae	Incidence (%)
■ Right ventricular failure	15
■ Moderate–severe TR	20
■ Bradyarrhythmias requiring pacing	20
■ Tachyarrhythmias requiring treatment	15
■ Subpulmonary obstruction	10
■ Reduced exercise capacity	>75
■ Pulmonary hypertension	10
■ Sudden death	1 (per year)

Nonelectrophysiologic consequences of the atrial level repairs are shown in Table 49.5 and for the arterial switch operation in Table 49.6.

Surgery for Transposition of the Great Arteries with Low Left Ventricular Pressure

Some circumstances may arise that will cause postponement of surgery beyond the safe period for an arterial switch. A neonate may be seriously ill with necrotizing enterocolitis, renal failure, or hemorrhage or may be premature or have low birth weight. A neonate may be geographically distant from a center offering the arterial switch operation; and, occasionally, a patient with TGA/VSD awaiting elective repair may have spontaneous partial or complete closure of the VSD resulting in an inadequate left ventricular mass. Surgical options for these patients include (a) primary atrial correction (see preceding) or (b) two-stage anatomic correction.

TABLE 49.6 Postoperative Sequelae Following the Arterial Switch Operation

Postoperative Sequelae	Incidence (%)
■ Supravalvar pulmonary stenosis ^a	~10
■ Supravalvar aortic stenosis ^a	<5
■ Neo-aortic root dilation	Essentially 100 ^b
■ Neo-aortic regurgitation	~50 ^b
■ Significant arrhythmia	<10

■ Hypertrophied bronchial collaterals ^a	<5
■ Abnormal coronary flow reserve	Unknown
■ Reduced exercise capacity	>75
■ Sudden death	Rare ^b

^aRequiring intervention.

^bIncreases with increasing duration of follow-up.

Pulmonary artery banding has been used to increase left ventricular afterload and stimulate hypertrophy. Indeed, the first successful anatomic repairs in patients with TGA/IVS consisted of placement of a pulmonary artery band, with or without a simultaneous systemic–pulmonary shunt, with an interval period of months before band removal and anatomic correction. Pulmonary artery banding can produce adequate muscle retraining within days (123), so that the preparatory procedure and the arterial switch operation can be done during the same hospitalization (rapid two-stage arterial switch) (124–127).

When this technique is used, left ventricular function may be extremely impaired following banding; therefore, a systemic–pulmonary artery shunt is frequently placed to ensure adequate pulmonary blood flow. The interval period between banding and correction is frequently characterized by a low output syndrome, most likely resulting from a combination of acute (fixed) right ventricular volume overload from the shunt and acute (transient) left ventricular dysfunction from the pulmonary artery band. Clinical improvement coincides with improvement in left ventricular function such that anatomic correction can be performed within 7 to 10 days in most cases.

Left Ventricular Preparation

There is little information as to just how late primary anatomic correction can be successfully performed. The normal postnatal decrease in pulmonary vascular resistance results in a rapid fall in left ventricular afterload following closure of the ductus arteriosus. With time, this leads to an inadequate left ventricular muscle mass to sustain systemic pressure immediately following the arterial switch operation. Although absolute guidelines are difficult to make, identifying a “prepared” left ventricle may be easier than defining an “unprepared” one; a left ventricle that can generate a normal (or near normal) systolic pressure for age and with normal posterior wall thickness/muscle mass will most likely be able to perform at systemic pressure following anatomic correction.

It is much more difficult to state when a left ventricle has become unprepared (128,129). In some cases, direct pressure measurements in the left ventricle or the ratio of left-to-right ventricular pressure may not be predictive of the capability of the left ventricle to perform systemic work. For example, in a neonate with immediate closure of the ductus and a prompt fall in pulmonary vascular resistance, the left ventricular systolic pressure can fall to less than half the systemic levels (or 25 to 30 mm Hg) as soon as 4 or 5 days after birth. This does not mean that the left ventricle is incapable of producing systemic work if the arterial switch is done at that time, but if left at low pressure for an additional period of time (perhaps beyond 2 to 3 months), this left ventricle would most likely be unable to support systemic work. Also, age alone does not necessarily dictate whether a left ventricle is unprepared, even in patients with TGA/IVS. A 6-week-old patient whose ductus has only recently closed will more likely have a prepared left ventricle than a 6-week-old patient whose ductus closed directly after birth. Finally, identifying the rate and degree of fall of pulmonary vascular resistance is difficult or impossible to do, especially if the patient presents for surgery in the 1- to 3-month age range.

Thus, it is frequently a difficult clinical decision as to when a patient's left ventricle is unprepared. Empiric criteria to determine adequate left ventricular preparation may include (a) an absolute left ventricular systolic pressure that is appropriate for age, (b) a left ventricular pressure at cardiac catheterization that is at or above 70% systemic levels (left-to-right ventricular ratio >0.7), or (c) left ventricular muscle mass that is within the normal range for body surface area.

Figure 49.40. Indices of late left ventricular function after primary arterial switch in 134 patients with TGA/IVS, 32 with TGA/VSD and 25 following a rapid two-stage arterial switch. Fractional shortening (A) and (B) myocardial contractility (the relationship of end-systolic stress to the rate-corrected velocity of fiber shortening is a load independent index of contractility) are expressed as the Z-score \pm 2 SD from the mean. Function appears better preserved following a primary repair compared with the two-stage approach. ASO, arterial switch operation; FS, fractional shortening; F/U, follow-up. (Data modified from Boutin C, Jonas RA, Sanders SP, et al. Rapid two-stage arterial switch operation: acquisition of left ventricular mass following pulmonary artery banding in infants with transposition of the great arteries. *Circulation* 1994;90:1304–1309.)

Although pulmonary artery banding remains the standard surgical method to “retrain” the left ventricle, other innovative approaches have included a percutaneously adjustable band (130), partial balloon occlusion of the main pulmonary artery with a percutaneously placed balloon-tipped catheter, systemic–pulmonary artery shunting alone, and a primary arterial switch with left ventricular assist in the perioperative period (128,129,131).

Following the preparatory procedure, usually performed through a midline sternotomy, anatomic correction is performed in a standard fashion based on the patient’s anatomy, with removal of the pulmonary artery band and takedown of the shunt (if present). Mortality following pulmonary artery banding may be as high as 10%, although the early postoperative course following the arterial switch seems comparable to that of primary repair.

Several follow-up studies have shown less-well preserved ventricular function in patients who undergo two-stage anatomic correction compared with those who undergo primary anatomic correction (Fig. 49.40) (80,124,132). Also, follow-up studies revealed a higher incidence of neo-aortic regurgitation and root dilation following two-stage repair.

Anatomic Correction without Coronary Translocation

In 1975, Damus, Kaye, and Stansel—in independent reports—proposed an arterial level repair without coronary translocation. The so-called Damus-Kaye-Stansel technique is now generally reserved for children with TGA and coronary artery patterns not suitable for transfer or for patients with DORV (Taussig-Bing type) with severe subaortic stenosis. The main pulmonary artery is transected and anastomosed in an end-to-side fashion to the ascending aorta. The coronary arteries are perfused in a retrograde fashion. The native aortic valve may be left intact. A VSD (if present) is closed to direct left ventricular blood to the native pulmonary (neo-aortic) valve. Finally, a right ventricular–pulmonary artery conduit is placed to establish a normal series circulation.

Long-term follow-up studies of the Damus-Kaye-Stansel operation are limited. Anecdotal experience suggests that the native aortic valve regurgitation is common in this group of patients, perhaps because of the lack of antegrade flow across the valve combined with the continued retrograde pressure load. This type of regurgitation has the physiologic sequelae of a wide pulse pressure and increased volume load on the systemic ventricle and results in a left-to-right shunt and pulmonary overcirculation; however, closure of the native aortic valve or subaortic region at surgery prevents decompression of a suprasystemic right ventricle in patients with conduit obstruction or in patients with elevated pulmonary vascular resistance. Thus, routine closure of the native aortic valve at the time of the Damus-Kaye-Stansel operation remains somewhat controversial.

In older infants and children with TGA/large VSD, anatomic repair sometimes can be achieved by using an intraventricular patch-tunnel technique that establishes a normal ventriculoarterial connection. Functionally, such patients with large VSD have maintained a hypertrophied left ventricle capable of assuming systemic afterload; many have had palliative pulmonary artery banding early in infancy. To construct a relatively straight tunnel that does not obstruct the pulmonary outflow tract, it is usually necessary to resect portions of the outlet (infundibular) septum and enlarge the VSD by resecting a portion of the interventricular septum that is anterior to the VSD. These segments of the septum do not carry the AV conduction axis, and the septal resection can make some defects subarterial in position even if they do not originally have this necessary condition for the intraventricular repair. Anatomically, the feasibility of intraventricular repair depends on the relationship of the VSD to the great arteries, the distances between the tricuspid valve and the semilunar valves, and the nature of the AV valve leaflets, particularly their chordae tendineae attachments. This operation is essentially the same as the intraventricular repair that is applicable to some patients of the subgroup of DORV characterized by the pulmonary trunk overriding an anterosuperior VSD (Taussig-Bing malformation).

Several other innovative techniques have been described for anatomic correction without coronary translocation, including creation of aortopulmonary tunnel (Aubert procedure) or baffling the left ventricular outflow to the non-translocated coronary ostia with a patch of native aorta or pericardium. Finally, the entire aortic root may be translocated to the left ventricle with biventricular outflow tract reconstruction.

Surgery for Transposition of the Great Arteries with Associated LVOTO

Direct surgical relief of severe LVOTO may be difficult and depends primarily on the anatomic type and severity of obstruction, which usually is directly related to the state of the interventricular septum and its alignment with the infundibular septum. In the older, palliated (septostomy or septectomy) infant with TGA/IVS, there is often a mild or moderate dynamic LVOTO, but this is clinically unimportant. Furthermore, the obstruction has only rarely been noted to progress during late follow-up after atrial switch repair. Predictably, this form of systolic dynamic LVOTO is reduced or eliminated in older infants with TGA/IVS following pulmonary artery banding as a left ventricular preparative procedure for secondary arterial switch repair.

Transpulmonary or transmitral resection has been performed for severe fixed obstruction caused by a short, discrete fibromuscular subvalvar shelf in patients with TGA/IVS. Because access is often limited and extensive resection may carry excessive risk of conduction abnormalities, residual pressure gradients have been common. If the obstruction is severe, with left ventricular systolic pressures at systemic (or suprasystemic) levels, and the pathology is not amenable to direct relief, an atrial switch operation with placement of a left ventricular-pulmonary artery valved conduit has been successfully used.

In the neonate or young infant with TGA/large VSD, some moderate LVOTO can function to prevent heart failure and limit early and rapidly progressing pulmonary vascular disease. As long as intercirculatory mixing and systemic arterial oxygen saturation are satisfactory and the peak systolic pulmonary artery pressure is low, intracardiac surgery can be safely delayed with careful follow-up regarding the pulmonary artery.

In the infant with TGA/large VSD and severe left ventricular outflow obstruction, there may be markedly restricted pulmonary blood flow and severe hypoxemia. In some neonates, a palliative systemic-to-pulmonary arterial shunt (Gore-Tex interposition shunt or classic Blalock-Thomas-Taussig shunt) may be performed, with intracardiac correction carried out at a later age. Alternatively, corrective surgery can be performed in early infancy.

One such procedure, the Rastelli operation (133), is a combination of intraventricular repair and placement of an extracardiac right ventricular to pulmonary artery conduit. The Rastelli repair has been considered the most appropriate operation for TGA with large VSD and extensive LVOTO because it achieves complete bypass of the LVOTO and an anatomic correction of the transposition pathology. In this operation (Fig. 49.41), the proximal main pulmonary artery is functionally divided either by pledgetted mattress suture closure of the subvalvar obstruction or by oversewing a stenotic pulmonary valve orifice (Fig. 49.42). The left ventricular output is directed to the aorta by placement of an intraventricular patch-tunnel technique. Finally, the right ventricle is connected to the proximal main pulmonary artery by means of a valved extracardiac conduit. The VSD must be of adequate size to permit unobstructed outflow from the left ventricle, and enlargement of

the defect by anterior excision of septal muscle may be necessary. Intracardiac repair with the Rastelli operation until recently has had an operative mortality of 20% to 30%, but more recently, operative survival of about 95% and midterm survival of about 90% are reported with good results, particularly in children older than 1 to 2 years of age.

Complications can result from unfavorable anatomic variants, such as a restrictive VSD or anomalous tricuspid valve connections to the infundibular septum that prevent baffling the left ventricle to the anterior aorta. As with other such complex repairs, residual VSD, late unexpected death, and myocardial dysfunction have been reported. As with all extracardiac conduiting operative techniques, there is concern about the functional longevity of the valved conduits. Improved results are noticeable with fresh or cryopreserved homograft-valved conduits compared with the previously used Dacron heterograft structures.

An interesting alternative corrective technique, termed REV (*Réparation à l'étage ventriculaire*) by LeCompte, has been used recently for patients with TGA and LVOTO. The REV procedure appears to have some advantages over the Rastelli operation: application in younger patients and avoidance of prosthetic extracardiac conduit and avoidance of intracardiac tunnel obstruction. This operation involves performing a high, anterior right ventricular incision and a radical excision of the outlet septum to create an unobstructed anterior right ventricular cavity; establishing a short and direct intraventricular tunnel from the LV to the aorta; closure of the pulmonary artery orifice; and reimplantation of the transected (and usually anteriorly translocated) pulmonary artery directly onto the right ventricular outflow cavity without a prosthetic conduit (134). A comparative study of the traditional Rastelli operation with the newer REV approach suggested that the REV allows complete repair earlier in infancy, is feasible in patients with anatomic contraindications to the Rastelli operation, and may reduce the need for reoperation and the prevalence of residual pulmonary outflow tract obstruction; (135) however, the life-long implications of pulmonary regurgitation following this newer operative approach require continued investigation.

Finally, posterior translocation of the aortic root and coronary arteries can be performed, with enlargement of the LVOT, with conduit placement from the right ventricle to the pulmonary arteries anteriorly, as originally described by Nikaidoh (136,137).

Controversy exists regarding the optimal initial management of the neonate or infant with severe hypoxemia and TGA/VSD with significant LVOTO. Arguments can be made that a Rastelli procedure should be performed in early infancy rather than a palliative systemic-to-pulmonary artery shunt. Although in an infant the Rastelli procedure still must be considered a palliative operation—a second operation for conduit replacement is inevitable—an early Rastelli repair results in a normal series circulation, avoidance of prolonged hypoxemia, and, presumably, a better long-term hemodynamic and neurologic outcome. Conduit replacement generally can be performed at low risk and with good results; therefore, many centers with expertise in neonatal and infant surgery have moved toward performing infant Rastelli repairs as the procedure of choice for the hypoxemic neonate or infant with TGA/VSD and LVOTO.

The arterial switch operation has been applied successfully in patients with TGA and certain types of LVOTO (138,139). Mild pulmonary valve abnormalities, dynamic or surgically remediable subpulmonary obstruction (e.g., AV valve tissue, a hypertrophied muscle of Moutaert, or a discrete membrane), or abnormal mitral valve attachments do not preclude application of the arterial switch operation in certain patients. Gradients measured preoperatively across the LVOT must be interpreted cautiously because there is frequently increased pulmonary blood flow in these patients. Left ventricular outflow gradients are typically significantly less after the arterial switch operation,

Figure 49.41. Rastelli operation for TGA/VSD and significant LVOTO. A–C: Details of surgical procedure. (Modified from Rastelli GC, McGoon DC, Wallace RB. Anatomic correction of transposition of the great arteries with ventricular septal defect and subpulmonary stenosis. *J Thorac Cardiovasc Surg* 1969;58:545–552.) A: Interior of right ventricle (RV) demonstrating relationship of VSD, tricuspid valve (TV), and aortic valve. B: Left ventricle is connected to aorta (AO) by tunnel patch extending between VSD and aorta. C: Completed repair with RV connected to the distal end of pulmonary artery (PA) by valved prosthetic conduit or (currently) homograft. D,E: Lateral angiograms with selective left ventricle (LV) and RV injections after Rastelli operation in 5-year-old. In (E), note the small (left-to-right) leak across tunnel patch (arrow), and (D) porcine (P) valved conduit (C) between RV and PA.

even if no surgical procedure is performed on the LVOT, as the blood flow across this region is reduced to normal (139).

Surgery for Transposition of the Great Arteries with Associated Right Ventricular Outflow Tract Obstruction

A spectrum of hearts exists from TGA with large subpulmonary VSD to {S,D,D} DORV (Taussig-Bing anomaly). These defects typically are characterized by varying degrees of anterior malalignment of the infundibular septum, subaortic narrowing/stenosis, aortic annular hypoplasia, a small hypoplastic arch, and coarctation or interruption of the distal aorta. If a coarctation is present (see also the section on Associated Anomalies), a VSD almost invariably coexists. Although more severe degrees of right-sided hypoplasia typically are associated with hypoplasia of the tricuspid valve and right ventricle and, not infrequently, left juxtaposition of the right atrial appendage, numerous treatment options are available for the subgroup of patients with an adequate-sized right heart.

In cases with only discrete coarctation, the coarctation can be repaired by a left thoracotomy with or without associated pulmonary artery banding. As pulmonary artery banding has been associated with progressive dilation of the neo-aortic root and propensity for neo-aortic regurgitation, many centers now limit pulmonary artery banding in these situations to cases with coarctation and multiple VSD. When pulmonary artery

banding is not performed, the arterial switch operation can be performed shortly after the child recovers from the coarctation repair. BAS should be performed prior to this repair so that following ligation of the ductus arteriosus (which is typically kept patent with a prostaglandin infusion), adequate mixing and arterial oxygen saturation may take place.

In cases of more significant proximal arch hypoplasia in association with coarctation or interruption, the entire corrective surgical procedure can be accomplished from the midline (140–142). This procedure involves arch reconstruction in a similar fashion to Norwood's reconstructive procedure for hypoplastic left heart syndrome, LeCompte maneuver to bring the (usually much larger) pulmonary arteries anterior to the reconstructed aorta, and an arterial switch operation with VSD closure.

Coronary artery patterns are more frequently unusual in these patients, and typically the anterior facing sinus gives rise to the right coronary artery and the left anterior descending, and the posterior sinus of Valsalva gives rise to the circumflex. The anterior course of the right coronary artery may complicate the repair; because an anterior malalignment VSD with subaortic narrowing frequently coexists in these patients, the coronary artery course may prevent or limit the size of the ventriculotomy necessary to relieve subaortic stenosis or to expose and close the VSD. A right ventricular–pulmonary artery conduit may be necessary in cases of severe subaortic obstruction or aortic (neopulmonary) annular hypoplasia. Care must be taken to avoid compression of the coronary arteries by the extracardiac conduit.

Figure 49.42. Preoperative (A) and postoperative (B) left ventriculograms in the same patient with TGA/VSD/left ventricular (LV) outflow tract obstruction. A: A transvenous (across the atrial septum) injection at 3 days of age. Posteriorly deviated conal septum (below a mildly hypoplastic pulmonary annulus) resulting in a malalignment type of VSD (*asterisk*). The branch pulmonary arteries (PA) are good sized. B: Retrograde left ventriculogram taken 4 years after the infant's repair (with an aortic homograft to establish right ventricular [RV] to PA continuity, not shown). The tunnel from LV to aorta (AO) is unobstructed. The blind-ending stump of main pulmonary artery fills with contrast (*double asterisk*). A tiny residual VSD is demonstrated (*arrow*).

Whereas single-stage corrective procedures for TGA/VSD/arch hypoplasia carry a significant mortality risk, alternative palliative surgical procedures have been less than satisfactory. Indeed, perhaps the worst results for atrial switch surgery are in patients with TGA, VSD, and associated arch hypoplasia. Palliative operations are particularly suboptimal in this subgroup of patients; therefore, an arterial switch operation/arch reconstructive surgery, albeit at high risk, is generally recommended for these patients.

Surgery for Right Ventricular Failure Following Physiologic Correction

With the growing recognition of progressive systemic (right) ventricular failure following physiologic correction (see preceding), with or without associated tricuspid insufficiency, numerous surgical procedures have been used in advanced, symptomatic patients. These include tricuspid valvuloplasty/replacement, cardiac transplantation, or anatomic correction.

Tricuspid valve surgery has been of limited success; this operation carries high mortality and morbidity rates and is frequently only a temporizing measure. Cardiac transplantation has been used in cases of significant, symptomatic ventricular (especially biventricular) dysfunction; indeed, TGA is the single most common anatomic diagnosis for patients with congenital heart disease listed in most cardiac transplantation registries. The life-long need for immunosuppressive therapy, the limited supply of donor organs, and the current mortality and morbidity risks make this radical therapy reserved for only the most symptomatic of patients.

A creative alternative approach of "retraining" and using the left ventricle (anatomic repair) together with takedown of the atrial repair was advocated by Mee et al. (143,144) and since then has been performed at other centers (145–147). Anatomic correction can be performed either by a standard arterial

switch operation with coronary translocation (see preceding) or, alternatively, transection of the main pulmonary artery with an end-to-side anastomosis and right ventricular-to-pulmonary artery conduit placement (Damus-Kaye-Stansel operation, see preceding). Both anatomic corrective procedures have their disadvantages. The arterial switch operation may be technically more difficult in the older patient with a prior physiologic correction because frequently dense adhesions are present that may restrict anterior mobilization of the branch pulmonary arteries and limit precise identification and adequate mobilization of the coronary arteries. A Damus-Kaye-Stansel operation may be technically easier to perform, but it requires the use of a prosthetic conduit from the right ventricle to pulmonary arteries.

Issues of left ventricular preparedness are defined even more poorly in this group of patients than in the unrepaired, cyanotic neonatal and infant subgroup (see also section on "Surgery for TGA with Low Left Ventricular Pressure"). The ability for the older child or adolescent's heart to hypertrophy following a pulmonary artery band, the rapidity with which this hypertrophy occurs, and the interval period necessary for adequate preparation are not yet established. Some patients may have a prepared left ventricle as a result of (a) coexisting subpulmonary stenosis or (b) pulmonary venous obstruction (leading to pulmonary artery and left ventricular hypertension). In the face of systemic or near systemic left ventricular pressure, anatomic correction with Senning or Mustard takedown can be performed as a single operation. In most cases, however, pulmonary artery banding is necessary to prepare the left ventricle.

Results of this approach are limited to a few series. Operative mortality is high (as high as 20% to 30%) (70) when considering both the preparatory and corrective procedures. Although follow-up studies have shown improvement in symptoms and systemic (now left) ventricular function, there has been a disappointingly high incidence of neo-aortic regurgitation in this group

of patients (148). Some have speculated that the pulmonary valve, if subjected to low pressure for many years, may be susceptible to neo-aortic regurgitation following anatomic correction. Thus, not only is the left ventricle unprepared; the pulmonary valve may be unprepared as well. Nonetheless, this innovative surgical approach continues to be used with modest success in patients with symptomatic right ventricular failure following physiologic correction. Longer follow-up certainly will be necessary to assess the long-term merits of this rather aggressive surgical approach.

Surgery for TGA/VSD and Pulmonary Vascular Obstructive Disease

Elevated pulmonary vascular resistance markedly increases the risk of surgery with closure of the VSD. Advanced pulmonary vascular disease characterized by calculated pulmonary vascular resistances >10 U or grade 4 (H–E) histologic changes is considered a contraindication to closure of the VSD. Extensive grade 4 (H–E) pathology has been observed even in patients with lower pulmonary vascular resistance levels of 6 to 8 U. Despite the advanced pulmonary vascular changes, the pulmonary artery oxygen saturation is higher than the aortic saturation in most patients. Palliative switch (either atrial or arterial) allows more effective pulmonary and systemic flows and a significantly improved systemic arterial oxygen saturation.

Palliative atrial switch repairs (without closure of the VSD) have been accomplished with low surgical risk and substantial hemodynamic and clinical benefit. In one series (149) concerned with 41 palliative Mustard procedures, operative mortality was 7%, late mortality was 5%, and actuarial survival was 92% at 7 years. After palliative atrial switch repair, the effective systemic blood flow is markedly increased. Mean systemic arterial oxygen saturations were increased in two series from preoperative levels of 68% to 74% to postoperative levels of 87% to 90%. This procedure should be reserved for patients in whom peripheral desaturation is a major cause of symptomatology because there is no favorable postoperative change in the pulmonary artery pressures or calculated pulmonary vascular resistances. The concept of the palliative Mustard operation also has been applied successfully to patients with pulmonary vascular disease with IVS by creating concurrently a VSD in the apical segment of the muscular septum: In one child, there was an increase of systemic arterial oxygen saturation from 46% preoperatively to 93% postoperatively. Fortunately, the inevitability of advanced pulmonary vascular disease, previously so tragically prevalent in older infants and children with TGA/large VSD, has been markedly reduced during the past two decades.

ACKNOWLEDGMENT

The author thanks Milton H. Paul, M.D., whose pioneering work in the diagnosis and management of TGA forms the basis for much of the data in this chapter.

Congenitally Corrected Transposition of the Great Arteries (Atrioventricular and Ventriculoarterial Discordance)

Joseph Atallah ■ Jennifer M. Rutledge ■ John D. Dyck

The language of corrected transposition can be difficult. Isolated ventricular inversion, double discordance, physiologically corrected transposition, and L-transposition are all terms that have been applied to congenitally corrected transposition of the great arteries (ccTGA). For the patient with ccTGA, situs solitus, and normal atrial arrangement, the systemic venous return joins the morphologic right atrium. This atrium is connected by a mitral valve with the morphologic left ventricle, which in turn supports a discordantly connected, transposed pulmonary artery (PA) (Fig. 50.1). The left atrium, receiving the pulmonary veins, connects through a tricuspid valve (TV) with the morphologic right ventricle (RV), which in turn supports a transposed aorta (Fig. 50.1). These atrioventricular (AV) and ventriculoarterial (VA) connections do occur in the setting of situs inversus. Patients with other abnormalities of situs and other AV connections are properly excluded from discussion here (1,2).

In ccTGA, the effects of ventricular inversion are potentially physiologically corrected by the associated TGA. That is, the path of venous blood returning to the heart leads to the PA and the path of pulmonary venous return leads to the aorta. However, even in the patient with no associated abnormalities, it is increasingly apparent that natural history and hemodynamics will be far from normal (3).

PREVALENCE, ETIOLOGY, AND MORPHOGENESIS

Corrected transposition is an uncommon lesion. Data from several sources would suggest a prevalence of 0.03 per 1,000 live births accounting for approximately 0.05% of congenital heart malformations (4–6). The majority of these patients will have situs solitus, and about 5% will have situs inversus (7).

Population-based studies continue to support the possible importance of environmental factors in the etiology of this condition (8). Still, the familial occurrence and molecular biology investigations suggest the importance of the genetic influence (9,10). It would seem wise therefore to continue to counsel a multifactorial etiology with a recurrence risk in first-degree relatives of approximately 2% (11).

Morphogenetically, the primitive cardiac tube, anchored at one end by the sinus venosus and at the other end by the truncus arteriosus, loops to the left (L-looped) and not to the right (D-looped) as in the normal heart (12). This abnormal cardiac looping brings the morphologic left ventricle to the right and the morphologic RV to the left. The origins of abnormal cardiac looping continue to be an area of active investigation (13,14). Most frequently, such abnormal looping of the ventricles is associated with a transposed VA connection.

MORPHOLOGY

Despite the relative rarity of corrected transposition, important studies and descriptions of the basic morphology have been published for some years (15–18). Advances in the surgical management of corrected transposition have occasioned reassessments of the pertinent anatomy (19,20).

As noted, some 5% of patients with corrected transposition will have situs inversus (7). Furthermore, approximately 25% of patients will demonstrate either dextrocardia or mesocardia (17). The ventricular topology (relative orientation of the ventricles) in corrected transposition places the RV to the left of the morphologic left ventricle. As a result of the abnormal looping, the ventricles conform to a left hand pattern (21). That is, if one places the palm of the hand against the right ventricular surface of the interventricular septum, the thumb in the inlet and the fingers in the outlet, it is necessary to use the left hand in ccTGA in contradistinction to the right hand in the normally D-looped ventricles. Further twisting can result in a more superior to inferior relationship of the RV to the left ventricle (22). The interventricular septum tends to a more sagittal or horizontal position resulting in one of the central features of AV discordance, that of malalignment of the atrial and ventricular septum. The atrial septum and ventricular septum meet at the crux of the heart. However, as the atrial septum continues anterior and to the right, it will deviate to a variable degree from the ventricular septum creating a variable gap that in extreme cases will go back as far as the crux (16). This concept of malalignment of the atrial septum and the ventricular septum has implications for the size and extent of the ventricular septal defect (VSD), the ventricular outflows, and the conduction system (23).

The AV valve on the right side has the features of a mitral valve with two papillary muscles and no insertion onto the interventricular septum. Penny et al. (24) have pointed out that 10% of mitral valves in this setting will demonstrate significant echocardiographic abnormalities. On the left, the AV valve has features of a TV. This valve frequently is abnormal with anterior positioning bringing the septal leaflet into the “gap” created by the septal malalignment at the membranous septum. This leaflet may thus form one wall of the left ventricular outflow tract (16).

Most frequently, AV discordance is associated with transposition of the great arteries (TGA) and a leftward anterior position of the aortic valve relative to the pulmonary valve, though this is not absolute (21). Freedom et al. (25) have shown that leftward anterior positioning of the aorta also may occur in the setting of complete transposition, double-outlet RV, anatomically corrected malposition, crossed AV connections, supero-inferior ventricles, and univentricular connections (26). The left ventricular outflow tract is deeply wedged between the left

Figure 50.1. Diagram of congenitally corrected transposition of the great arteries demonstrating atrioventricular and ventriculoarterial discordance. Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Figure 50.2. Associated anomalies in congenitally corrected transposition of the great arteries. (A) Ventricular septal defect (VSD); (B) Ebstein anomaly of the tricuspid valve; (C) multiple-level left ventricular outflow obstruction; (D) atrial septal defect (ASD).

and right AV valves and is therefore more readily subject to obstruction. The pulmonary valve is most often in fibrous continuity with the mitral valve.

The leftward anterior aorta is supported by a muscular infundibulum and is not in fibrous continuity with either AV valve. Obstructive lesions of the right ventricular outflow tract and aorta perhaps have been underemphasized. Several reports suggest the higher frequency of this problem in association with severe left AV valve regurgitation. Systemic outflow obstruction may take the form of functional and/or true aortic valve atresia as well as obstructive anomalies of the aortic arch (27–29).

ASSOCIATED LESIONS

Patients with congenitally corrected transposition and no associated abnormalities are in fact the exception, with associated anomalies occurring in well over 90% (30). The most frequent abnormalities include VSD, left ventricular outflow tract obstruction, and anomalies of the left-sided TV (Fig. 50.2).

VENTRICULAR SEPTAL DEFECT

VSDs occur in approximately 80% of hearts with corrected transposition (18). The defects are most often perimembranous and a consequence of the atrial and septal malalignment (16). This positioning will put them in a subpulmonary position and in approximation to the septal leaflet of the left-sided TV. The defects are often large with anterior extension and therefore suitable for intraventricular tunneling. Other defects such as the subarterial or muscular defect do occur but are unusual.

PULMONARY OUTFLOW OBSTRUCTION

Obstruction to the outflow tract of the morphologic left ventricle is identified in 30% to 50% of patients with ccTGA and atrial situs solitus. Such pulmonary outflow tract obstruction rarely occurs in isolation at the valve or infundibular level, but usually

is associated with a large VSD. In about one-third of patients with a VSD and pulmonary outflow tract obstruction, abnormalities of the morphologic TV are observed as well. The left ventricular outflow tract obstruction may be muscular, reflecting wedging of the subpulmonary outflow tract between the infundibular septum and the ventricular free wall, with contributions from the right-sided ventriculoinfundibular fold. Fibrous tissue derived from the membranous septum may participate in left ventricular outflow tract obstruction. Tissue tags derived from the tricuspid or mitral valve or stenosis of the pulmonary valve itself also may obstruct flow into the pulmonary trunk. Such tissue tags are likely the most common obstructive lesion (31).

LESIONS OF THE MORPHOLOGIC TRICUSPID VALVE

Abnormalities of the morphologic TV are intrinsic to hearts exhibiting ccTGA. Although at autopsy about 90% of hearts exhibit some abnormality of the morphologic TV, a clinically apparent functional disturbance during life is considerably less often manifest. The most common and important underlying pathology is dysplasia of the valve, with or without displacement of the septal or posterior leaflets of the TV. Anderson et al. (32) has described the features associated with “Ebstein” anomaly of the left-sided TV and has suggested along with others that these valves in general may represent a poor substrate for repair. Both the morphologic TV and on occasion the mitral valve can be seen to straddle the ventricular septum. It is of course very important to recognize this anomaly preoperatively (33).

CORONARY ARTERY ANATOMY

Changing approaches to the surgical management of corrected transposition, including the so-called double switch procedure, have refocused attention on the coronary artery anatomy. In general, the coronary arteries originate from the posterior-facing sinuses of the aortic valve. In patients with atrial situs solitus and ccTGA, the coronary arteries show a mirror-image

distribution. The right-sided coronary artery has the epicardial distribution of a morphologic left coronary artery. The main right-sided coronary artery bifurcates into circumflex and anterior descending branches, whereas the left-sided coronary artery runs in the left AV groove and gives rise to infundibular and marginal branches.

Several investigators have demonstrated a variable pattern of coronary artery anomalies. In an angiographic study of 13 children, investigators reported a prevalent pattern of ‘coronary artery–ventricular concordance’ (34). In a 14-specimen study, McKay et al. (35) observed the persistent origin of the sinus node artery from the circumflex artery and speculated on its course along the medial side of the right atrial wall. They commented on the potential surgical risk of damaging the artery during an atrial baffle procedure or atriotomy repair. In that same report, a correlation between commissural malalignment and eccentric coronary ostia was observed. Ismat et al. (36) analyzed 20 specimens and found 7 with eccentric ostia. Rare cases of an isolated origin of the sinus node artery from a coronary sinus have also been reported (37). The largest pathologic study (46 specimens) was undertaken by Uemura and colleagues. They reported a 76% incidence of a relatively “normal” pattern with the right and left coronaries originating from the left and right facing sinuses, respectively. Anomalies were found in 11 specimens. Single coronary artery was the most common in four, with two originating from the right and two from the left facing sinuses. A main coronary branch coursing anterior to the pulmonary trunk was found in 96% of the specimens, and a large coronary branch crossing the right ventricular outflow tract was found in 61% of the specimens. The latter finding is of most importance when considering a ventricular to PA conduit. Chiu et al. (38) described a segmental approach to the coronary anatomy. From their study of 62 patients, they concluded: (a) the proximal coronary pattern at the aortic sinus depends on the aortopulmonary rotation, (b) the peripheral coronary pattern depends on the atrial situs and apical position or the so-called apicocaval ipsilaterality, as well as the ventricular looping (38). A good understanding of the type and degree of variability of the coronary anatomy in patients with congenitally corrected transposition is crucial in the era of “double switch” surgical approaches to these patients.

SPECIALIZED CONDUCTION TISSUES

The conduction system in patients with ccTGA is abnormal and potentially unstable. The extensive works done by Anderson, Becker, Losekoot, and others, have elucidated the presence of normal and abnormal conduction tissue (17,39–42). The sinoatrial (SA) node lies in its normal position in relation to the atrial situs. The AV conduction tissue, on the other hand, is abnormal. The classic description is that of two AV nodes. A normal posterior AV node located at the apex of the triangle of Koch but with no AV bundle, and an abnormal right anterior AV node giving rise to the penetrating AV bundle. The latter is located anterosuperiorly in the area lateral to the pulmonary–mitral valve continuity, underneath the opening of the right atrial appendage. Its AV bundle has a superficial course along the anterior aspect of the subpulmonary outflow tract and superior left ventricular wall. The bundle then courses onto the upper interventricular septum from which it descends and branches. If a VSD is present, the anterior AV bundle courses along its anterosuperior margin.

The conduction tissue abnormality is not universal to all patients with ccTGA. The reason why certain patients had a normal AV node and AV bundle may have been elucidated by Hosseinpour et al. (23). They hypothesized that the development of an AV bundle from the normal posterior AV node to the summit of the interventricular septum

is anatomically hindered by the atrial and ventricular septal malalignment. The degree of malalignment is related to the size of the left ventricular outflow tract and the pulmonary trunk. They showed that patients with congenitally corrected transposition and a normal conduction system were frequently characterized by the presence of pulmonary atresia or significant pulmonary stenosis. These anatomical variants resulted in a lesser degree of atrial and ventricular septal malalignment. Therefore, a correlation is made between the size of the LV outflow tract, the degree of septal malalignment, and the presence of normal AV conduction tissue. It is thought that the normal conduction tissue is “in addition to” rather than “instead of” the abnormal anterior conduction system. In patients with both conduction systems straddling the anterosuperior and inferoposterior margins of a VSD, there can exist a sling-like bundle located over the anterior margin of the VSD and connecting both AV bundles, as described by Monckeberg (42).

CLINICAL FEATURES

The clinical features of patients with ccTGA have been well documented (43,44). Patients with isolated ccTGA should be asymptomatic in childhood, though there is a high incidence of clinical problems in adults (30). In childhood, the timing and severity of symptoms, in general, reflects the associated lesions. Infants with ccTGA may come to attention because of bradycardia, (with or without heart failure) reflecting high-degree AV block, tachyarrhythmia, cyanosis reflecting inadequate pulmonary blood flow, and/or congestive heart failure. Congestive heart failure may reflect a cardiac arrhythmia, but more likely indicates a large VSD, dysplasia or displacement of the left-sided morphologic TV with regurgitation, obstructive anomalies of the aortic arch, or a combination of these anomalies.

The older child may be referred to a pediatric cardiologist for evaluation of a loud second heart sound (and thus the clinical suspicion of PA hypertension), but this is most uncommon in the neonate. The physical examination only occasionally raises the possibility of AV and VA discordance. Clearly, the presence of clinical features suggestive of “mitral regurgitation” in a neonate should prompt consideration of ccTGA and an abnormal systemic AV valve.

In some neonates with ccTGA, regurgitation of the systemic AV valve may be massive, and such patients may have such profound cardiomegaly that they are considered clinically to have classical Ebstein anomaly of the TV (with concordant AV and VA connections). Organic or functional aortic atresia has been described in these patients, and common to them all is a terribly disorganized and deficient morphologic TV and an extremely thinned morphologic RV.

ELECTROCARDIOGRAPHIC FEATURES

In the patient with normal atrial situs and discordant AV and VA connections who is free of significant associated intracardiac malformations, the direction of the frontal P-wave axis is normal and, therefore, positive in leads I, II, III, and aVF, but negative in aVR. Clearly, the position of the heart within the thorax does not influence the P-wave vector or axis.

The electrical activation of the ventricles in the normal heart begins in the interventricular septum and is directed from left to right and in a slightly anterior direction as well. This initial activation is responsible for the normal pattern of Q waves in the precordial leads: a qR pattern in V₆ and an Rs in V₁. The absence of Q waves in the left precordial leads is seldom observed in normal children, but 25% of normal neonates may not demonstrate a Q wave in V₆.

In corrected TGA, the interventricular septum has a more or less sagittal disposition and is oriented from left posterior to right anterior. With ventricular inversion, both its surfaces and ventricular bundle branches are inverted, and thus the sequence of initial activation is oriented from right to left and usually in a more superior and anterior direction. This results in a reversal of the normal Q wave pattern in the precordial leads: Q waves are present in the right precordial leads but are absent in the left precordial leads. This pattern of reversal is appreciated less commonly when the heart is right-sided or when there are confounding associated lesions producing pressure or volume overload (15).

If one were to catalogue the electrocardiographic change identified in patients with corrected transposition, they would include reversal of Q wave disposition in the precordial leads with QS complexes in the right precordial leads, large Q waves in leads III and aVF, and left axis deviation.

With the precarious nature of the conduction system, as previously noted, the occurrence of congenital and postsurgical complete AV block is significant. Complete AV block is present in about 4% of patients at birth and the overall lifetime incidence is 20% to 30% (45). The most important feature is the increasing prevalence of complete heart block in the corrected transposition population during follow-up, with an estimated rate of 2% per year after diagnosis (45,46). Despite the development of surgical techniques to reduce the incidence of complete heart block at surgery, this problem continues to be significant and progressive (47). It is imperative for this reason alone that all patients with corrected transposition have long-term follow-up.

RADIOGRAPHIC FEATURES

Although the chest radiograph is thought to provide useful information in the diagnosis and evaluation of the patient with ccTGA, these observations are probably more germane to the older infant or child than to the neonate with this disorder. The chest radiograph of the patient with levocardia, atrial situs solitus, and ccTGA may reflect the abnormal ventriculoarterial junction. The most common spatial relationship of the great arteries in corrected TGA is a side-by-side or oblique one, with the aorta to the left. This is manifest in the plain chest radiograph in the frontal projection as a deformity of the left upper mediastinal border characterized by a convex prominence at its middle and upper portions with a mild convexity in the anticipated position of the pulmonary trunk (Fig. 50.3). This shadow represents the levopositioned ascending aorta, which originates from the left-sided morphologic RV. A levopositioned aorta is not diagnostic of discordant AV and VA connections.

ECHOCARDIOGRAPHY

The examination of the patient with complex AV and VA connections should begin with the definition of situs, which can be achieved adequately by cross-sectional ultrasound examination of the great vessels in the abdomen. In the patient with situs inversus, the aorta lies on the right of the spine, with the inferior vena cava (IVC) on the left and the morphologic right atrium on the left. This is important since 5% of cases of corrected transposition will occur in the setting of situs inversus. Patients with situs ambiguous will demonstrate either interruption of the IVC, or the aorta and IVC on the same side of the spine. By definition, these patients cannot demonstrate true ccTGA, but nevertheless, this may be important in the

Figure 50.3. Chest radiography in congenitally corrected transposition of the great arteries. No intracardiac abnormalities. Note levopositioned aorta (arrows).

differential diagnosis. In some patients, despite an ambiguous atrial situs, the atria may be relatively well lateralized.

By moving up from the cross-sectional (horizontal) view of the abdominal vessels to the subcostal view of the heart, cardiac position can be determined accurately. This is crucial as 25% of patients with ccTGA will demonstrate either dextrocardia or mesocardia. In addition, this approach should make clear other abnormalities of the spatial relationships of the chambers, such as crisscross AV connections and superoinferior ventricles.

The subcostal views are important in the identification of a case of ccTGA because they allow imaging of all chambers and vessels. From this position, the first clue to the presence of AV discordance may be the significant malalignment between the atrial and ventricular septa that occurs in this condition (Fig. 50.4).

Figure 50.4. Subcostal four-chamber view of congenitally corrected transposition of the great arteries with dextroposition, demonstrating malalignment of atrial septum and ventricular septum (arrows) with inlet ventricular septal defect.

Figure 50.5. Four-chamber view (A) and pathologic specimen (B) demonstrating morphologic features of congenitally corrected transposition of the great arteries. (LA, left atrium; LV, left ventricle; MLV, morphologic left ventricle; RA, right atrium; TV, tricuspid valve.)

In all cases, the sonographer should look for features that define the morphologic right versus the morphologic left ventricle. These features include the apical displacement of the AV valve of the RV relative to the left (exaggerated in the presence of an Ebstein-like malformation and absent in the presence of an AV septal defect or a large perimembranous inlet VSD), a trileaflet (tricuspid) versus a bileaflet (mitral) AV valve, septal attachments of the AV valve of the RV (TV), the presence of a moderator band in the RV, an irregular mural endocardial surface of the RV relative to the smooth endocardial surface of the left ventricle, and a round or triangular shape to the right ventricular cavity versus an elongated or ellipsoidal shape to the left ventricular cavity. The subcostal four-chamber view is important in obtaining information about these features (Fig. 50.5).

The long-axis views from the chest tend to be more vertically oriented than in the normal heart, and the two great arteries are seen to arise in parallel, confirming the presence of TGA. As the ventricular septum is often horizontally oriented in ccTGA, the long-axis views can be confusing, particularly in the presence of a large perimembranous inlet VSD. In this case, the pulmonary valve can be seen related to either AV valve, creating some confusion with respect to VA connection. Nevertheless, the long-axis views are particularly important in establishing the mechanisms of possible outflow tract obstruction to either the aorta or PA (Fig. 50.6).

Short-axis views from the chest, on the other hand, prove extremely useful. At the level of the aortic and pulmonary valves, the aorta with its coronary arteries usually is demonstrated in an L-position (leftward and anterior) relative to the bifurcating PA (Fig. 50.7). This relationship of the great arteries, although typical, is not absolute. Short-axis sweeps will confirm the VA connection to be discordant, as suspected from the subcostal views, and will demonstrate the orientation of the ventricular septum as well as the AV valve leaflet anatomy and papillary muscle distribution.

By tilting the transducer upward from the four-chamber view, one can demonstrate how the pulmonary outflow tract from the right-sided left ventricle is deeply wedged between the two AV valves. Indeed, the pulmonary outflow tract is even more deeply wedged than the aorta in normal hearts and subject to obstruction from more than one source.

The apical four-chamber views are especially useful for reviewing the AV valve anatomy with particular reference to Ebstein malformation of the left AV (tricuspid) valve.

Color-flow Doppler is used to quantitate AV valve regurgitation. This view also clearly shows the usual perimembranous inlet VSD.

A high left parasternal view oriented in the sagittal plane, similar to the so-called ductal cut position, not only will demonstrate the ductus arteriosus but, because of its usual leftward and anterior position, will also open up the entire aortic arch. The suprasternal views, in fact, often demonstrate the aorta less well. Demonstration of the branching pattern of the aorta is important because a right aortic arch is more common than previously believed (18%).

Atrial defects are seen in about 12% of cases and are most usually of the secundum type. Echocardiographically, the atrial septum, as in the normal heart, is best imaged from subcostal and foreshortened four-chamber views with color-flow Doppler, confirming the usual left-to-right atrial shunt. Alternatively, ccTGA is occasionally associated with an AV septal defect. Such an occurrence may complicate the

Figure 50.6. Long-axis view in congenitally corrected transposition of the great arteries. Note posterior pulmonary artery (PA). Subpulmonary stenosis with accessory atrioventricular tissue from both right and left atrioventricular valves. (Ao, aorta.)

Figure 50.7. Parasternal short-axis view of anterior levopositioned aorta with posterior pulmonary artery bifurcation. (Ao, aorta; PA, pulmonary artery.)

diagnosis of AV discordance, as described already, but accurate echocardiographic identification is certainly possible.

The left AV valve can display a wide range of structural abnormalities. Perhaps the most common is a variable degree of dysplasia with less displacement than seen in the usual form of Ebstein anomaly of the TV in the patient with concordant connections. These features are best demonstrated echocardiographically from the four-chamber (Fig. 50.8) and modified short-axis views. As the usual functional problem is valvular regurgitation, this will be readily evaluated with color-flow Doppler. Stenosis of the valve in this situation is unusual; nevertheless, inflow velocities should be evaluated. Significant “Ebstein-like” malformation of the left AV valve may be associated with right ventricular hypoplasia and occasional subaortic obstruction. These possible associations should be sought. Other anomalies may affect the left AV valve, including a supra-valvar stenosing ring and varying degrees of AV valve override and straddle. As the usual VSD in ccTGA is perimembranous inlet, posterior straddling of the left AV valve is significantly more common than straddling of the right AV valve, which requires an anterior VSD. There is little doubt that echocardiography is the method of choice for

Figure 50.8. Apical four-chamber view in congenitally corrected transposition of the great arteries. Dilated LA from tricuspid regurgitation and Ebstein-like displacement of septal leaflet. The arrow indicates the level of the tricuspid annulus. (LA, left atrium; MV, mitral valve; TV, tricuspid valve.)

Figure 50.9. Apical four-chamber view in congenitally corrected transposition of the great arteries demonstrating herniation of the tricuspid valve septal leaflet (TV) into the ventricular septal defect. Arrow indicates septal leaflet of TV.

establishing the presence or absence of straddling of the AV valve. The parasternal short-axis and four-chamber views are particularly useful in this regard. Again, the presence of AV valve straddle should be a clue to the possibility of ventricular hypoplasia.

Abnormalities of the right AV valve usually are not described among the common anomalies associated with ccTGA. A necropsy series however, suggested that up to 55% of cases demonstrated a wide variety of abnormalities of the left AV valve. Parachute deformity of the right-sided mitral valve has been described (48). The subcostal four-chamber view generally demonstrates the right AV valve to best advantage.

A VSD will be seen in approximately 80% of patients with ccTGA. Most frequently, these defects can be described as perimembranous with inlet or posterior extension. Such defects, by the nature of their posterior extension, are predisposed to demonstrate partial occlusion by the apically displaced septal leaflet of the TV (Fig. 50.9) and also are positioned to allow straddling of the TV. Such anatomy is best demonstrated in parasternal short-axis views and apical or subcostal four-chamber views. Outlet defects and muscular defects are seen less commonly. The ventricular apex is often not well seen from the subcostal position; therefore, apical muscular VSDs are best sought in the apical four-chamber view.

The unique anatomy of the left ventricular outflow tract to the PA is best demonstrated from the subcostal position by directing the transducer anteriorly from the four-chamber view. Pulsed or continuous-wave Doppler assessment of the outflow tract also is best undertaken from this position, as flow will be most parallel to the Doppler line of interrogation. As stated, the pulmonary outflow tract is wedged deeply between the right and left AV valves. Obstruction can result from one or more possible mechanisms: abnormality of the valve itself; prominent right-sided, muscular, ventriculofundibular fold with the muscular infundibular septum causing subpulmonary obstruction; and accessory tissue from either the right or left AV valve or aneurysmal tissue about the inlet VSD causing obstruction of the left ventricular outflow tract (Fig. 50.10).

Abnormalities of the right ventricular outflow tract to the aorta are somewhat unusual but have a number of interesting aspects. Obstruction or severe regurgitation of the left AV valve commonly is associated with outflow tract obstruction. In fact, in the setting of severe left AV valve regurgitation, one must be certain that the aortic obstruction is not simply functional. The aortic annulus is separated from the body of

Figure 50.10. A: Subcostal view in patient with congenitally corrected transposition of the great arteries and subpulmonary obstruction. Accessory tissue is seen from both left and right atrioventricular valves. B: Pathologic specimen cut in same plane as echocardiogram. (LV, left ventricle; PA, pulmonary artery.)

the ventricle by a complete muscular infundibulum; therefore, muscular outflow tract obstruction may seem dynamic. In addition, obstruction may be due to subaortic membrane, valvar stenosis, and accessory AV valve tissue (49). The subaortic area is best imaged in the left parasternal or occasionally a subcostal position.

As with subaortic obstruction, coarctation of the aorta often is associated with severe left AV valve regurgitation, VSD, or hypoplasia of the RV. The diagnosis can be made from the high left parasternal position.

With an anteriorly positioned aorta, imaging of the coronary arteries is excellent (Fig. 50.11). Seventy-six percent of patients will have a coronary distribution concordant with the ventricular anatomy; however, single coronary artery anomalies and others occur.

The fetus with congenitally corrected transposition could come to the attention of the fetal sonographer for several reasons, including family history, detection of cardiac abnormality on prior obstetrical ultrasound examination, and hydrops fetalis. Hydrops fetalis in congenitally corrected transposition may result from severe left AV valve regurgitation or complete AV block with bradycardia. The cardiac anatomy and cardiac rhythm are demonstrated readily by fetal echocardiography. The occurrence of AV block leading to the detection of congenitally corrected transposition in utero is unusual. The fetus with severe AV valve regurgitation and ccTGA has a very guarded prognosis and may undergo spontaneous abortion. A study of 34 fetuses documents the most valuable features of the ultrasound diagnosis of corrected transposition in the fetus (50).

Transesophageal echocardiography appears to be well suited to the examination of the patient with congenitally corrected transposition. It provides a reliable window in the older patient

who has had prior surgery and has a limited transthoracic window. Furthermore, the transesophageal echocardiography window is ideal for examination of those structures critical to the patient with this disorder, including the atrial septum, left and right AV valves, and the inlet ventricular septum. Several studies have documented the advantages and disadvantages of transesophageal echocardiography (51,52).

Figure 50.11. Cross-sectional view of levopositioned aorta demonstrating a coronary artery (arrow). PA, pulmonary artery.

Figure 50.12. Three-dimensional view of tricuspid valve in congenitally corrected transposition of the great arteries demonstrating dysplasia of septal leaflet. (ant, anterior leaflet; post, posterior leaflet; sept, septal leaflet.)

Three-dimensional echocardiography is increasingly used in the setting of ccTGA (53,54). We use this modality to assess the left AV and have found it useful (Fig. 50.12). Establishing the nature of left ventricular outflow tract obstruction and the relationship of the VSD to the aorta are other areas where we have found three-dimensional echo to be of great value.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) allows both anatomic and physiologic diagnostic information, particularly for the assessment of the systemic RV. We have found MRI particularly useful in the assessment of patients prior to contemplated anatomic repair (Figs. 50.13 and 50.14). Studies to date have

Figure 50.13. Frontal cut of T1-weighted MRI in congenitally corrected transposition of the great arteries with dextroposition, ventricular septal defect, and pulmonary atresia. (Ao, aorta; RV, right ventricle.)

Figure 50.14. Frontal cut of T2-weighted MRI, in congenitally corrected transposition of the great arteries with mesocardia, ventricular septal defect, and pulmonary atresia. (Ao, aorta; LV, left ventricle; PA, pulmonary artery; RV, right ventricle.)

shown good correlation with other modalities in terms of functional evaluation and have confirmed the concerns regarding systemic right ventricular function (55–59). In addition, MRI proves to be useful and reliable in patients with PA banding for LV retraining. It allows accurate assessment of the LV mass/LV volume ratio, used as one of the determinants of adequate LV retraining for proceeding with the double switch operation.

CARDIAC CATHETERIZATION

Anatomic and functional detail provided by 2-D and 3-D echocardiography and MRI have reduced the need for routine preoperative catheterization in the majority of patients with ccTGA. In the recent past, diagnostic right and left-sided heart catheterization was performed prior to intracardiac repair, focusing on imaging the PA and coronary anatomy (60,61). Diagnostic catheterization remains important in the preoperative assessment of patients in whom pulmonary vascular resistance may be elevated (long-standing VSD shunt, severe left-sided AV valve regurgitation) along with the response to pulmonary vasodilators, in patients with suspected aortopulmonary collaterals or unexplained cyanosis, and less commonly in those with abnormal coronary artery anatomy that is not well-defined with noninvasive imaging. The adult with unrepaired ccTGA may still benefit from preoperative catheterization, especially in the setting of arrhythmias, ventricular dysfunction, long-standing intracardiac shunting, or unexplained cyanosis (62). Cardiac catheterization remains a part of the assessment of left ventricular hemodynamics in patients undergoing left ventricular retraining prior to anatomic repair (63).

Since ccTGA of the great vessels may occur with cardiac malposition, noting the catheter course in the abdomen to identify the course of the IVC or aorta aids in the diagnosis of the underlying situs and malposition. Observations about the course of the catheter may be important in recognizing the abnormal position of the great arteries in relation to the ventricles as well. Using anteroposterior and lateral fluoroscopy,

Figure 50.15. Angiogram, A-P projection with contrast injection in left ventricle in congenitally corrected transposition of the great arteries with pulmonary atresia and ventricular septal defect (arrows). Note vertical position of ventricular septum (Ao, aorta; LV, left ventricle.)

their course can be determined. In patients with situs solitus and levocardia, the PA lies medially and posteriorly, with the venous catheter following a course close to the spine. The aorta lies anteriorly and along the left cardiac border.

Because of the anterior position of the AV node and the intrinsically fragile conduction system, patients with ccTGA are at higher risk of developing heart block during catheter manipulation, especially, but not invariably, when attempting access into the PA. Thus, it is always important to have available a system for emergent transvenous pacing during the procedure itself.

ANGIOCARDIOGRAPHY

Angiocardiography today is not performed without prior echocardiographic or MRI imaging. These modes of imaging should establish the diagnosis and also should indicate the relative topography of the ventricular septum. In most patients with ccTGA, the ventricular mass is aligned about a septum that is much more sagittal than in the normal heart (Fig. 50.15). A horizontal ventricular septum also is well described in patients with AV discordance. These observations of the disposition of the ventricular septum are important to the determination of the axial projection for angiocardiography.

Assuming the usual position of the ventricular septum, a frontal and lateral left ventriculogram, perhaps with 20 to 25 degrees of right anterior oblique (RAO), should profile the ventricular septum, the left ventricular outflow tract, and the mitral inflow (Fig. 50.16). A similar projection can be used for the injection in the morphologic RV. Obviously, if there are defects in other portions of the ventricular septum, the axial projections will have to be modified and expanded. The character of the subpulmonary obstruction is best imaged by selective injection of contrast into the morphologic left ventricle. In the setting of VSD, adding 20 to 25 of RAO will demonstrate to advantage both the VSD and the left ventricular outflow tract obstruction. The functional status of the left AV valve is perhaps best assessed by echocardiography and color Doppler, but right

Figure 50.16. A single-outlet aorta (Ao) in a patient with atrioventricular discordance. This left ventriculogram (LV) demonstrates a large ventricular septal defect (VSD).

ventricular angiography will also add information (Fig. 50.17). The character of subaortic stenosis, admittedly uncommon, may best be demonstrated by right ventricular angiography. Varying degrees of obliquity may be required to profile the small left ventricle or the VA connection of double-outlet RV.

The pulmonary arteries and their bifurcation are best imaged by a selective injection of contrast into the pulmonary

Figure 50.17. Severe systemic atrioventricular valve regurgitation (arrow) demonstrated by injection of contrast into the morphologic right ventricle (RV). The left atrium (LA) is severely enlarged.

arteries with craniocaudal angulation. A degree of right or left anterior obliquity will focus on the right or left PA, respectively.

The aorta and the coronary arteries can be profiled by aortography, filmed in the frontal and lateral projections. The coronary arteries originate from the posterior-facing sinuses, and selective coronary angiography may be necessary to obtain adequate demonstration of the anatomy.

NATURAL HISTORY AND MANAGEMENT

ccTGA is a complex and unusual form of congenital heart disease. As such, it takes time to accumulate experience, and then meaningfully study the natural history, surgical outcomes, and results of changes in surgical management.

The underlying problem with AV and VA discordance may be the issue of the RV as the systemic ventricle. There is however, a very high frequency of associated lesions, which, in their turn, tend to have quite different pathophysiologic effects on systemic right ventricular function. VSDs are volume loading. Pulmonary outflow obstruction will alter pulmonary blood flow, volume loading, and right ventricle–left ventricle interaction. Tricuspid regurgitation will both volume load the ventricle and reduce its afterload. The complex interactions of these anatomic and physiologic variables complicate outcome analysis.

MEDICAL MANAGEMENT

The neonate with ductal-dependent pulmonary blood flow requires immediate institution of intravenous prostaglandin to maintain patency of the arterial duct until such time that a stable source of blood supply to the lungs can be surgically constructed. Similar management is required for the infant who has severe coarctation of the aorta or interruption of the aortic arch. The medical management of the associated lesions thereafter dominates early medical management. Later, the medical management is likely to focus on systemic AV valve regurgitation and heart failure. The appropriate use of diuretics along with afterload reduction and beta-blockade may be required.

PACING

A significant proportion of patients will develop spontaneous or postoperative complete heart block. AV block frequently occurs in the setting of associated cardiac anomalies or results in significant bradycardia, necessitating permanent pacing. Depending on the patient's size, venous anatomy, residual intracardiac lesions, and type of surgical repair, pacing can be endocardial via a transvenous approach, epicardial, or a combination of the two. For heart block, selective site RV apical or LV apical pacing is preferred after physiologic repair or anatomic repair, respectively. The latter also is preferred after PA banding. The indication for and role of biventricular pacing and cardiac resynchronization therapy (CRT) in ccTGA patients with significant heart failure and ventricular dyssynchrony has been explored (64). In fact, the first reported case of CRT pacing in congenital heart disease involved a patient with ccTGA (65). The placement of a transvenous CRT system is challenging due to the unusual coronary sinus and great cardiac vein anatomy (66). The latter would allow CRT of the systemic morphologic RV. In patients with an anatomical repair (described below), the coronary sinus is not transvenously accessible and a hybrid or epicardial approach is required for CRT of the morphologic left ventricle. Data on the outcome of CRT in ccTGA patients remain limited (67–69).

UNOPERATED NATURAL HISTORY

Early natural history is impacted significantly by the severity of associated lesions and surgical management. Although there have been repeated case reports of long-term survival with ccTGA, this is probably unusual (70,71). A few investigators who have tried to separate natural history from associated lesions and surgical outcomes suggest a different set of probabilities. Beauchesne et al. (72) followed 44 unoperated patients for up to 144 months and found that the majority (59%) had grade 3 or greater systemic AV valve regurgitation and that many of these demonstrated significant systemic RV dysfunction and were symptomatic. Presbitero et al. (30) have followed 18 patients, again pointing to systemic AV valve regurgitation and ventricular dysfunction as major concerns. In a large multi-institutional study, Graham et al. (73) found that while patients without associated lesions had a lower occurrence rate of heart failure and systemic ventricular dysfunction than those with associated lesions at a given age, these problems tended to increase in frequency with advancing age in both groups.

CONVENTIONAL SURGERY AND OUTCOMES

Conventional surgery for ccTGA includes several options based largely on the underlying associated lesions and their hemodynamic effects. PA banding or systemic to PA shunting has been used for palliation of increased or decreased pulmonary blood flow, respectively. VSD closure may be undertaken as a primary procedure or following debanding. Techniques for reducing the surgical complication of heart block following defect closure have been described (47). Left ventricle to PA outflow tract obstruction may be locally resected or managed with placement of a left ventricle to PA conduit. TV regurgitation has been managed with repair or replacement. However, valve dysplasia which frequently is severe, along with surgical series showing recurrent or progressive regurgitation after repair, suggest that valve replacement is the preferred option when possible. When complicated by significant AV valve straddle or ventricular hypoplasia, management leading to “Fontan” type palliation has been successful. Finally, for the patient with poor ventricular function, with severe tricuspid regurgitation, or with aortic atresia, cardiac transplantation may be the most successful approach.

Many series assessing the long-term outcomes of conventional surgical approaches and factors thought to determine outcome have been reported (74–81). Immediate surgical results clearly have improved, and surgical risk is likely to be 3% to 10%. Hraska (77) reported 5-year survival rates at 75% and 10 year at 68%. These results would appear to be remarkably similar to those reported by the other groups. Reoperations for conduit replacement and systemic AV valve repair/replacement are frequent and may approach 40% over 10 years. Risk factor analyses for a poor outcome repeatedly identify “Ebstein” malformation of the TV, the degree of tricuspid insufficiency, systemic right ventricular dysfunction, and complete heart block as important.

RIGHT VENTRICULAR DYSFUNCTION AND TRICUSPID REGURGITATION

Ventricular dysfunction and AV valve regurgitation are, of course, linked through the pathophysiologies of volume loading, ventricular and annular dilation and distortion, and right ventricular–left ventricular interaction. In the setting of corrected transposition, this is complicated by the frequency of congenital dysplasia of the TV and the impact of the other associated lesions.

The RV as the systemic ventricle relative to the left ventricle may be disadvantaged because of poor geometry, a lower ejection fraction, and lower coronary flow reserve (82,83). In the setting of simple transposition after atrial switch repair, studies of RV function give evidence of ongoing right ventricular dysfunction (84,85). Overall, however, right ventricular function may be preserved for many years. Studies in corrected transposition patients are limited, but tend to confirm the impression of systemic right ventricular dysfunction (82,86). Investigators of several series have reported a tendency toward worsening of systemic right ventricular function after conventional biventricular repair (78,87). The potential causes of this observation may be multiple, including complex alterations in right ventricular–left ventricular interaction, and the effects of surgical intervention itself.

While intimately connected to the issue of systemic right ventricular dysfunction, several studies have drawn specific attention to the importance of TV regurgitation. Prieto et al. (88) in a study of 40 patients with corrected transposition concluded that tricuspid insufficiency was the single most important factor associated with poor outcome and that the occurrence of systemic right ventricular dysfunction almost always was linked to long-standing tricuspid regurgitation. Acar (89) concluded that TV function depended upon the loading condition of both ventricles and upon septal geometry. Nevertheless, the cause of death after TV replacement most frequently is progressive systemic ventricular dysfunction (90).

The relationship between systemic right ventricular function and tricuspid regurgitation was most recently evaluated by the group from the Mayo Clinic. Mongeon et al. (91) hypothesized that patients with preserved ventricular function at the time of TV replacement would maintain preserved ventricular function long term. In a retrospective analysis of 46 patients, preoperative systemic ventricular ejection fraction as assessed by echocardiography was an independent predictor of ventricular function at ≥ 1 year after operation. This study is the first to suggest that surgery for TV regurgitation should be considered while systemic right ventricular function is preserved and may halt the deterioration of ventricular function long term in the majority of patients.

Several studies have focused on the impact of PA banding on systemic right ventricular function and AV valve regurgitation. In a series where banding was used for left ventricular conditioning prior to arterial switching, it has been suggested that PA banding may improve systemic ventricular function and AV valve regurgitation through a mechanism involving septal shift (92). In another series, Winlaw et al. (93) did not

find significant improvements in AV valve regurgitation but did find clinical improvement. Success at achieving biventricular repair was associated with the age at which banding was undertaken, with younger patients benefiting most. In the report by Jahangiri et al. (94), PA banding likely more often improved tricuspid regurgitation primarily by altering pulmonary blood flow and thereby altering loading conditions for the systemic RV. Neonatal PA banding has also been reported with similar results (95).

Patients with low left ventricular (subpulmonary) pressures and a deconditioned left ventricle require “retraining” prior to a double switch procedure. A strategy of progressive PA banding is performed to increase the pressure load on the left ventricle and promote left ventricular hypertrophy. The adequacy of banding can be assessed intraoperatively with echocardiography or with the use of conductance catheters to assess pressure–volume relationships, or with postoperative echocardiography, MRI, or cardiac catheterization. Suggested requirements for proceeding to double switch operation include LV pressure $\geq 70\%$ to 80% systemic, LV mass/LV volume ratio >1.5 , normal LV wall thickness for a systemic LV, and normal LV function after PA banding.

OUTCOMES OF THE “DOUBLE SWITCH” OR ANATOMIC REPAIR FOR ccTGA

The relatively poor outcomes associated with conventional surgery combined with considerations of the potential for progressive right ventricular dysfunction and tricuspid regurgitation has led to an exploration of alternative surgical approaches to the patient with ccTGA. Ilbawi et al. (96) first reported the anatomic repair of corrected transposition as opposed to the standard physiologic repair. The approach combined atrial switching (Mustard or Senning procedures) with intraventricular rerouting of the VSD, such that the anatomic left ventricle would carry on the role of the systemic ventricle and the anatomic RV would become the subpulmonary ventricle after a RV to PA conduit (Fig. 50.18). They subsequently reported their series of anatomic repairs (97). The pathologic anatomy of corrected transposition that could potentially preclude such an approach has been reviewed (19,20). Relative or absolute contraindications to the “double switch” might include a restrictive VSD, specific coronary artery anatomy, ventricular hypoplasia by more than 50%, AV valve straddle and anomalies of the mitral valve. Imai (98) was the first to

Figure 50.18. A,B: Congenitally corrected transposition of the great arteries following double-switch repair. A: Inferior limb of atrial baffle to the right ventricle. (B, baffle; LV, left ventricle; RV, right ventricle.) B: Ventricular septal defect (VSD) tunneling left ventricle to aorta. (Ao, aorta; PVA, pulmonary venous atrium.)

report a true “double switch” procedure involving both an atrial level switch and a full arterial level switch with coronary artery transfer (100). Subsequently, there has been a significant number of reports of anatomic repairs involving both ventricular level rerouting and/or arterial switching with some series large enough to address risk analysis (99–104). Complications of these often lengthy procedures can be expected to include those of the atrial switch (sinus node dysfunction, supraventricular dysrhythmias, baffle obstructions, and baffle leaks), the ventricular switch (subaortic obstruction, aortic regurgitation, conduit obstruction, or regurgitation), and/or the arterial switch (coronary artery obstructions, aortic valve incompetence, pulmonary arterial obstruction).

Left ventricular dysfunction following the anatomic repair operation may be relatively common. Quinn et al. (105) reported the outcome of 44 patients following double switch in which LV retraining was required in 11. By multivariate analysis, the completion of LV retraining predicted death/transplantation, the development of moderate-to-severe LV dysfunction, or both. Moderate to severe LV dysfunction was seen in 6/11 patients with prior retraining compared to 6/33 patients without retraining. Similarly, the Boston group has reported on the determinants of late LV dysfunction following anatomic repair (106).

The quality of life of patients after the anatomic repair compared to patients with nonanatomic repair and a systemic RV has recently been reported. Initial data showed comparable results, with lower school performance in the anatomic repair group (107).

In summary, when addressing the complex patient with ccTGA, the surgeon will need to choose between the risks and benefits of physiologic, anatomic, and on occasion, single ventricle type repairs.

CONCLUSION

Corrected TGA is an unusual congenital heart defect characterized by AV and VA discordance. The etiology, morphogenesis, and morphology are complex and fascinating to consider. The clinical picture is dominated by the pathophysiology of associated cardiac anomalies. Long-term follow-up of conventional surgical approaches is disappointing and has led to novel surgical approaches aimed at restoring normal AV and VA connections. Early results may be promising, but final assessment of the evidence requires further long-term follow-up.

Double Outlet Right Ventricle

Gail E. Wright ■ Katsuhide Maeda ■ Norman H. Silverman
Frank L. Hanley ■ Stephen J. Roth

DEFINITION

Double outlet right ventricle (DORV) is a type of ventriculoarterial connection in which both great arteries arise 50% or more from the right ventricle (RV). This chapter focuses on DORV with concordant atrioventricular (AV) connection with two ventricles. DORV may occur in univentricular hearts, particularly in the constellation of heterotaxy syndrome, and with AV discordance.

Although there were reports of hearts with DORV anatomy as early as 1893, the term double outlet right ventricle came into use in 1957 at the time of the first surgical repair of a patient with this lesion at the Mayo Clinic (1,2). Prior descriptions, including the original report in 1949 of what is now known as Taussig-Bing heart, included DORV variants as a form of partial transposition of the great arteries (3–5). There has been much debate about this terminology. For the purposes of this chapter, DORV is considered within the spectrum of conotruncal defects, with some forms exhibiting transposition physiology in which the pulmonary arterial oxygen saturation is higher than the aortic oxygen saturation. However, DORV and transposition are considered distinct anatomically, because discordant ventriculoarterial connections are core to the anatomic definition of transposition. In 1961, Neufeld et al. (6–8) developed a classification of DORV with and without pulmonic stenosis (PS). Subsequently in 1972, Lev et al. (9) categorized many types of DORV. Shortly thereafter, Sridaromont et al. (10,11) reported on hemodynamic and angiocardiographic correlations of anatomic variants. DORV nomenclature was reviewed more recently in the Congenital Heart Surgery Nomenclature and Database Project (12,13).

INCIDENCE

DORV accounts for fewer than 1% of all congenital heart defects. Its incidence is approximately 0.06 cases per 1,000 live births (14). There is no known racial or gender predilection, and no associated genetic defect has been identified.

MORPHOLOGY

DORV falls within the morphologic spectrum of conotruncal defects. As with much of congenital heart disease, the physiology

and treatment of these defects derive from the embryology and morphology.

With the exception of truncus arteriosus, which occurs due to failure of septation, other conotruncal defects are essentially rotational defects. The development of the conal septum drives that rotation. The variability among the individual lesions is best understood in terms of the spectrum of development of the conal septum, which determines the relative position of the two semilunar valves to the ventricles. The more conal muscle present beneath a semilunar valve, the more that valve is pushed superiorly and anteriorly, and the more likely it is that the associated great artery will align with the RV (15,16).

In the normal heart, the pulmonary valve sits up on the conus, a circular tube of muscle, and is positioned anteriorly and superiorly (17). In contrast, the aortic, mitral, and tricuspid valves are all attached to the central fibrous body of the heart. The conal muscle beneath the aortic valve largely resorbs, leaving the aorta positioned inferiorly and posteriorly (Fig. 51.1).

In conotruncal defects, there is a spectrum between hearts in which no conus exists beneath the aorta, as seen in tetralogy of Fallot, and hearts in which no conus exists under the pulmonary valve, as with transposition of the great arteries (Fig. 51.1). At each end of this spectrum, it is “all or nothing” in terms of the conus. DORV falls in the middle of the spectrum, with forms that have variable amounts of conus under each semilunar valve scattered across the continuum (18).

One common form of DORV is anatomically and physiologically similar to tetralogy of Fallot (19). There is a nearly normal length of conus beneath the pulmonary valve and minimal conus beneath the aortic valve. Consequently, there is no aorto-mitral continuity, and the pulmonary valve is anterior and superior. At the other end of the spectrum, another DORV variant has conus mostly under the aortic valve but has a small amount of conus under the pulmonary valve, resulting in the loss of pulmonary-mitral continuity. This form is morphologically and physiologically similar to transposition of the great arteries. In the middle is a type that has equal bilateral conus, such that the great arteries are side by side, with neither vessel tucked in posteriorly. Between the “tetralogy type” and the “transposition type,” there are many “shades of gray”—that is, DORV variants that have neither aorto-mitral nor pulmonary-mitral continuity and have variable distribution of conal septum (Fig. 51.1). These variations are more ambiguous both anatomically and physiologically and should be approached with an individualized management plan.

Common nomenclature for the types of DORV—for example, DORV with subaortic ventricular septal defect (VSD), DORV

Figure 51.1. Development of the conal septum in the fetus, in the normal heart, and in different types of DORV. In the fetus, there is a circular tube of muscle, the conus, beneath each great artery. The distribution of conal muscle is equal beneath the aorta and the pulmonary artery.

In the normal heart, the pulmonary valve sits up on the conus, and is positioned anteriorly and superiorly. The conal muscle beneath the aortic valve largely resorbs, leaving the aorta positioned inferiorly and posteriorly.

In DORV variants, the spectrum of distribution of conal muscle beneath each great artery determines the relative position of the two semilunar valves to the ventricles. The more conal muscle present beneath a semilunar valve, the more that valve is pushed superiorly and anteriorly.

“Tetralogy type”: One end of the spectrum—nearly normal length of conus beneath the pulmonary valve and minimal conus beneath the aortic valve. Pulmonary valve is anterior and superior. No aorto-mitral continuity.

“Shades of gray”: Between the “tetralogy type” and the “transposition type,” there are many “shades of gray”—variants with bilateral conus that have neither aorto-mitral nor pulmonary-mitral continuity and have variable distribution of conal septum. Neither of the great vessels is tucked in posteriorly.

“Transposition type”: At the other end of the spectrum—large amount of conus under the aortic valve with relatively little under the pulmonary valve. Aorta is pushed anteriorly and superiorly, resulting in rightward positioning of the aorta relative to the pulmonary artery. No pulmonary-mitral continuity.

NOTE: Although 2-D diagrams and images demonstrate the conus as a “tear drop,” it is important to note that in three dimensions, it is a circular tube of muscle.

Yellow, subaortic conus; Green, subpulmonary conus; Ao, aorta; PA, pulmonary artery; RV, right ventricle; LV, left ventricle; TGA, transposition of the great arteries; TOF, tetralogy of Fallot.

with subpulmonic VSD, and DORV with doubly-committed VSD—gives the impression that VSD position creates the difference, and that the relationship of the great arteries does not change (9,11). In fact, however, across the spectrum of DORV, it is the rotation of the great arteries, driven by conal development, that changes, not the position of the VSD. The VSD is constant; it is almost always a typical conoventricular VSD located in the perimembranous area and extending into the trabecular ventricular septum, with the upper part of the defect bordered by the lower edge of the conus. Emphasis on the influence of infundibular development unifies the conceptual approach to the spectrum of defects that constitute DORV. Due to the degree of morphologic variability, the description of an individual patient's heart with DORV must

include the associated relationship of the great vessels and the VSD to be most meaningful.

PS is by far the most common lesion associated with DORV. It occurs in approximately 50% of patients and may be valvar or subvalvar. Secundum atrial septal defects are seen in 25% of all types, whereas primum defects are seen in the 8% of DORV patients with AV canal defects. Multiple other associated lesions have been reported at low rates: patent ductus arteriosus, right aortic arch, subaortic stenosis, additional muscular VSDs, left superior vena cava (SVC) to the coronary sinus or left atrium, intact ventricular septum, and mitral valve anomalies including mitral atresia (9,10,20–22). Coronary artery anomalies occur in about 10% of patients—the most common being the anomalous

Figure 51.2. Coronary artery anomalies are of particular importance, because they may alter considerations for surgical repair due to their effect on feasibility of conduit placement or coronary transfer. CT angiograms demonstrate anomalous coronary origins and the relationship of the coronaries to the sternum well. **A:** CT angiogram, 3-D reconstruction: The right coronary artery (RCA) arises anteriorly and passes just under the sternum. LCA, left coronary artery; PA, pulmonary artery; Ao, aorta. **B:** CT angiogram, 3-D reconstruction: In a different patient, the RCA arises anomalously and crosses anterior to the aorta. Ao, aorta; RCA, right coronary artery.

origin of the anterior descending coronary artery from the right coronary artery. However, coronary artery anomalies are of particular importance, because they may alter considerations for surgical repair due to their effect on feasibility of conduit placement or coronary transfer (23) (Fig. 51.2). Likewise, associated aortic arch coarctation, hypoplasia, or interruption—also found in about 10% of patients—significantly increases the complexity of surgical repair when present (24,25).

CLINICAL FEATURES—COMMON VARIANTS

The clinical features and pathophysiology of DORV are determined by the morphologic variant (22). Even within the same subtype, there can be substantial variability in the clinical presentation. Historically, cardiac catheterization with angiography and hemodynamic assessment were used routinely for diagnostic evaluation. Currently, however, transthoracic echocardiography can identify all of the essential anatomic features in most cases, and the echocardiogram along with bedside pulse oximetry provides definitive diagnosis of the pathophysiology noninvasively (26). For patients with complex aortic arch anatomy, angiography may also be needed (27,28). Magnetic resonance imaging (MRI) is helpful to further define the relationship between the VSD and the semilunar valves in cases in which it is not clear which way to baffle the VSD during reparative surgery (29–32). In a minority of patients, for example those for whom the technical feasibility of a two-ventricle repair is debatable, cardiac catheterization is used to define pulmonary vascular resistance to determine suitability for a Fontan operation. Hemodynamic assessment via cardiac catheterization may also be necessary for another small subset of patients in whom the effects of streaming are variable and less apparent (10).

“TETRALOGY TYPE”

The most common variant is the “tetralogy of Fallot type,” with most of the conus under the pulmonary valve and minimal conal septum under the aorta (Fig. 51.1). This variant, also known as “DORV with subaortic VSD with PS,” is seen in approximately 40% of cases (9,11). The pulmonary valve is positioned anteriorly and superiorly, and the aorta overrides the interventricular septum. Blood from the left ventricle (LV) passes through the VSD to the aorta. The cardiovascular pathophysiology is determined predominantly by the degree of PS, which generally increases over time in early infancy. Typically there is progressive, dynamic obstruction to pulmonary blood flow at the subvalvar level, leading to oxygen saturations between 80% and 90% at baseline, with further desaturation during agitation. There is the potential for hypercyanotic spells as in tetralogy of Fallot. The cardiovascular exam is notable for a long, harsh systolic ejection murmur, loudest at the left upper sternal border and caused by the subvalvar PS. Since the VSD is not pressure restrictive, there is no additional VSD murmur. Infants with this anatomy may present as cyanotic neonates if there is severe PS, but more often the lesion is detected due to an evaluation performed because of a murmur. Cyanosis may not be present for several weeks, but after that time, it gradually worsens. The chest radiograph demonstrates normal to mildly diminished pulmonary vascular markings. The electrocardiogram is notable for right axis deviation and a right ventricular hypertrophy pattern, with rR', qR, or rsR' pattern; these findings are not, however, sufficiently specific to be diagnostic. Echocardiography can clearly define the essential anatomic features (Fig. 51.3A,B). In the parasternal long axis view, the absence of mitral–aortic continuity is shown as well as the presence of a large VSD. Subcostal views highlight the narrow subpulmonic tunnel. The apical four-chamber view demonstrates the

degree of aortic override over the crest of the interventricular septum along with two dimensions of the pathway for closure of the VSD to the aorta. Attention must be given to the chordal attachments of each AV valve and their relationships to the VSD. The diagnosis may be made with fetal echocardiography; accurate assessment of the relationships of the great vessels and the VSD are possible prenatally with enough precision to guide surgical planning in most cases with tetralogy features (33–35).

Surgery is indicated to relieve the obstruction to pulmonary blood flow and to septate the circulations. For this type of DORV, surgical outcomes are excellent in both neonates and older infants. Surgical repair as a neonate is indicated when there is severe limitation to pulmonary blood flow. In most patients, however, surgery is performed electively between 2 and 4 months of age before the infant becomes excessively cyanotic or develops hypercyanotic spells.

“TRANSPOSITION TYPE”

The second most common variant is the “transposition type” of DORV, with a large amount of conal tissue beneath the aorta and relatively little beneath the pulmonary artery (Fig. 51.1). Other designations for this variant, noted in approximately 20% of cases, include “Taussig-Bing anomaly” or “DORV with subpulmonic VSD” (9,11,36–38). In this type, the aorta is pushed anteriorly and superiorly, resulting in rightward positioning of the aorta relative to the pulmonary artery. There is no pulmonary–mitral continuity. The pathophysiology is determined by streaming of blood such that most of the highly oxygenated blood from the LV passes through the VSD into the pulmonary artery, whereas most of the deoxygenated blood from the RV flows directly into the aorta. Thus, there is transposition physiology with a pulmonary arterial oxygen saturation that is higher than the aortic oxygen saturation.

Figure 51.3. Echocardiographic views, CT angiogram image, and pathologic specimen of anatomy in “Tetralogy type.” **A:** Echocardiogram, parasternal long axis view: (**Left panel**) Note lack of mitral–aortic continuity due to conal septum beneath the aortic valve (*arrows* mark the conal septum). (**Right panel**, same image with addition of color flow mapping) There is no flow disturbance through the ventricular septal defect, which is large and not pressure-restrictive. RV, right ventricle; LV, left ventricle; LA, left atrium; AO, aorta. **B:** Echocardiogram, subcostal coronal view: (**Left panel**) This image demonstrates both great arteries arising from the RV, with conal septum separating the aorta and the pulmonary artery. (**Right panel**, same image with addition of color-flow mapping) Color-flow mapping demonstrates mild obstruction in the subvalvar area beneath the pulmonary valve due to conal muscle. RV, right ventricle; LV, left ventricle; PA, pulmonary artery; AO, aorta; CS, conal septum.

Figure 51.3. (Continued) C: Computed tomography angiogram, oblique image: Similar to the echo subcostal view in 3B, CT angiography demonstrates both great arteries arising from the RV, with conal septum separating the aorta and the pulmonary artery. RA, right atrium; AO, aorta; PA, pulmonary artery; CS, conal septum; RV, right ventricle. (Courtesy of Frandics Chan, M.D., Ph.D., Stanford University) D: Pathologic specimen: The VSD is bounded by the underside of the aortic valve and cradled in the arms of the septomarginal trabeculations. The pulmonary artery is walled off by infundibular muscle. **, = borders of the VSD, white arrow = coronary artery orifice, black arrow = PMC, papillary muscle of the conus, Ao, aorta; PA, pulmonary artery; TVAL, tricuspid valve anterior leaflet; TVSL, tricuspid valve septal leaflet. (Courtesy of Diane Spicer, B.S., University of Florida.)

These patients present as cyanotic neonates, with the degree of arterial hypoxemia determined by the degree of streaming and the presence and size of the interatrial connection and ductus arteriosus. The chest radiograph demonstrates a normal-sized cardiac silhouette and mildly increased pulmonary vascular markings. Echocardiography usually provides comprehensive anatomic definition with this type as well (Fig. 51.4). In particular, subcostal views can demonstrate the precise relationship of the great vessels and the length and extent of the subaortic conus. When there is significant subaortic narrowing, there is associated aortic arch hypoplasia, which must be imaged from the suprasternal notch views. There must be a high index of suspicion for arch hypoplasia or interruption in neonates with severe subaortic narrowing (Fig. 51.5). Angiography, either via computed tomography or via cardiac catheterization, may be required when the arch anatomy cannot be fully visualized by echocardiography, especially in the face of a patent ductus arteriosus (Fig. 51.6).

Surgery is indicated to improve systemic oxygenation and is performed in the neonatal period. Surgical repair also establishes continuity between the LV and the aorta. When there is severe hypoxemia with a small interatrial communication, balloon atrial septostomy improves atrial mixing sufficiently to allow for non-emergent surgical repair in the first weeks of life, as is often true for newborns with d-transposition of the great arteries and intact ventricular septum.

"VSD TYPE"

The third common variant is the "VSD type" of DORV, which is also known as "DORV with subaortic VSD without PS." This variant is seen in approximately 15% of patients (9,11). In this type, there is slightly more conal tissue beneath the pulmonary

valve than the aortic valve such that the pulmonary valve is still anterior, but sufficient conus is beneath the aorta so that the aorta is rotated rightward (Fig. 51.1). Because there is bilateral conus, there is loss of mitral-aortic continuity; however, the subaortic conus is not as large as in the "transposition type," and the subpulmonary conus is not as large as in the "tetralogy type." The pathophysiology is that of a large VSD with significant left-to-right shunting and pulmonary overcirculation. As for the other two common variants, echocardiography can typically define the essential features of the intracardiac anatomy. Infants typically present with signs of congestive heart failure as the pulmonary vascular resistance falls between 4 and 8 weeks of age. Failure to thrive gradually ensues, as is seen in other lesions with excessive pulmonary blood flow.

Surgery is indicated to eliminate the left-to-right shunt with associated high pulmonary blood flow and volume load on the left heart. The timing of surgery is elective. However, surgical outcomes for this variant are excellent in early infancy, and medical management with diuretics and nutritional supplementation is only temporizing, so there is no benefit in deferring surgery once symptoms of pulmonary overcirculation arise.

CLINICAL FEATURES OF LESS COMMON VARIANTS

DORV encompasses a broad range of variation in the spectrum of conotruncal development. In all forms there is bilateral conus, but the distribution of the amount of conus beneath each semilunar valve is different (Fig. 51.1). Consequently, there are many "shades of gray" subtypes. In these, the distribution of conal tissue is closer to 50:50 beneath each semilunar valve.

Figure 51.4. Echocardiographic views of anatomy in “transposition type.” **A:** Subcostal coronal view: Aorta and pulmonary artery both arise from the RV and are side-by-side in the same plane with the aorta rightward. Relatively large subaortic conus (*small arrow*) separates the aorta and pulmonary artery. Aortic valve and ascending aorta are hypoplastic. SVC, superior vena cava; AO, aorta; PA, pulmonary artery; RV, right ventricle. **B:** Subcostal coronal view: Aorta and pulmonary artery both arise from the RV with the aorta rightward and slightly anterior. Large subaortic conus separates the aorta and pulmonary artery with narrowing of the egress from the LV due to the conal septum and tricuspid valve cordal attachments. RV, right ventricle; LV, left ventricle; PA, pulmonary artery; AO, aorta; CS, conal septum; TV cord, tricuspid valve cordal attachment. **C:** Parasternal long axis view: Aorta and pulmonary artery both arise from the RV with the aorta rightward and anterior. There is tissue beneath the pulmonary valve (*small arrow*); due to this subvalvar obstruction, the pulmonary artery is relatively small compared to the aorta. RV, right ventricle; LV, left ventricle; AO, aorta; PA, Pulmonary artery; A, atrium. **D:** Subcostal coronal view: Aorta and pulmonary artery both arise from the RV, side-by-side, in the same plane with the aorta rightward. Aortic valve leaflet tips marked with small arrows. Note subaortic obstruction due to large subaortic conus (*vertical arrow*). Due to the subaortic obstruction, the aortic valve and ascending aorta are relatively hypoplastic. VSD demarcated by arrows at the crest of the interventricular septum and at the small rim of conal septum beneath the pulmonary valve. RV, right ventricle; LV, left ventricle; AO, aortic valve; PA, pulmonary artery.

Figure 51.4. (Continued) E: Fetal echocardiogram in Taussig-Bing heart: Aorta and pulmonary artery both arise from RV, side-by-side with the aorta rightward. Small arrow marks conal septum. RV, right ventricle; LV, left ventricle; AO, aorta; PA, pulmonary artery; DAO, descending aorta.

In these variants, because the anatomy is more ambiguous, the diagnostic evaluation should be as comprehensive as possible, and serial assessments over time using complementary imaging modalities may be needed to plan the optimal approach and timing of surgical repair. Often even with a comprehensive preoperative diagnostic evaluation, the ultimate decision making will depend on intraoperative inspection of the anatomy and potential approaches to VSD closure by the surgeon.

Discussion of all of the possible morphologic combinations of DORV is invigorating to the experienced cardiologist and surgeon because of the uniqueness of each patient; however, it may be cumbersome for those gaining mastery of the lesion. One of the less common variants, DORV with noncommitted VSD, warrants specific attention because it presents difficult management decisions, and as such constitutes a high-risk subgroup. Additionally, patients with this variant, who in the past either were marginally palliated in infancy or were deemed inoperable, are now resurfacing as adolescents and young adults for consideration for technically challenging operations.

DORV WITH “NONCOMMITTED VSD”

DORV with a “noncommitted VSD” occurs in slightly <10% of cases (9,11). In this subtype, there is a significant amount of conus beneath each great vessel such that neither vessel is truly posterior, and the interventricular connection is not directly related to either great vessel. Since both great arteries are rotated somewhat superiorly, the typically positioned VSD opens primarily into the body of the RV. Alternatively, there may be a muscular VSD connecting to the inlet or apical part of the RV. The pathophysiology of these variants is complete admixture. There may be little or no obstruction to flow to the pulmonary or systemic circulations, or there may be some degree of subvalvar and valvar pulmonic stenosis resulting

either in balanced circulations or inadequate pulmonary blood flow. Complete repair in early infancy is seldom technically feasible. No operation may be necessary early in life, but if PS causing hypoxemia is present, a palliative aortopulmonary shunt may be required to increase the systemic oxygen level.

As with other forms of DORV, echocardiography is used to define the relationships of the great vessels, the relative position of the VSD to the great vessels, the anatomy of the subvalvar regions and the semilunar valves, and the adequacy of both ventricles (Fig. 51.7). Particular attention must be paid to the attachments of the AV valves, especially the tricuspid valve leaflets, which may be interposed between the VSD and the great arteries in a way that may impact VSD closure. Echocardiography, angiography, and MRI are complementary in defining a potential surgical pathway for VSD closure. MRI in particular allows for 3-D imaging of the potential pathway from LV to aorta and also may provide superior imaging in older patients whose body habitus precludes excellent transthoracic echocardiographic imaging. Cardiac catheterization provides definition of the size and shape of the VSD and its relationship to the great vessels, and it allows assessment of the pulmonary vascular resistance. Catheterization is advisable when it remains debatable whether the VSD can be closed to direct flow to either great vessel; for these patients, a Fontan operation is typically the fallback option intraoperatively.

Because these repairs are technically complex, and because the VSD patch may encroach upon the RV cavity, repair of this subtype is generally deferred until the patient is at least several years of age. Young adult patients presenting for evaluation without detailed information about their prior care warrant special attention. Because serial data or multiple prior echocardiograms for comparison of the anatomy are often not available, obtaining multiple complementary imaging studies is critical. Although intraoperative inspection of the anatomy is always necessary, obtaining comprehensive anatomic detail preoperatively minimizes the additional time on cardiopulmonary bypass required to determine the optimal operation. This is an important consideration since the bypass times for these patients are typically prolonged due to the technical complexity.

OTHER LESS COMMON VARIANTS

DORV with “doubly committed VSD” occurs in approximately 10% of cases (9,11). In this variant, only fibrous as opposed to muscular conal septum separates the leaflets of the pulmonary and aortic valves (Fig. 51.8). Both great vessels override the crest of the ventricular septum. The VSD is in the typical position, cradled between the limbs of the septomarginal trabeculation. The pathophysiology is predominantly left-to-right shunting with pulmonary overcirculation. Surgical VSD closure directs flow from the LV to the posterior and rightward aorta.

DORV occurs with mitral atresia and with AV canal defects in the constellation of heterotaxy syndrome. DORV is also noted with AV discordance.

HISTORY OF SURGICAL REPAIR OF DOUBLE OUTLET RIGHT VENTRICLE

The first successful correction of DORV was performed by Kirklin and associates in 1957 and subsequently by Barratt-Boyes and associates in 1958 (39, 40). Although these first repairs were for “VSD type” DORV, since that time, a large number of surgical reports have appeared including “tetralogy

Figure 51.5. Series of views of a pathologic specimen demonstrating Taussig-Bing anomaly with interrupted aortic arch. These images are all from the same specimen, which has been opened from different perspectives in each view to demonstrate different anatomic elements optimally. **A:** The specimen was dissected into the RV. The delimiting coronary artery, the LAD, is shown. Both the aorta and the pulmonary artery arise from the RV. The aorta is smaller and rightward. The innominate artery and left common carotid arise from the ascending aorta. The ductus arteriosus arises from the pulmonary artery. The ductus arteriosus supplies the descending aorta and the left subclavian artery. RV, right ventricle; LV, left ventricle; LAD, left anterior descending coronary artery; MPA, main pulmonary artery; LPA, left pulmonary artery; RPA, right pulmonary artery; Ao, aorta; PDA, patent ductus arteriosus; IA, innominate artery; LCC, left common carotid artery; DAo, descending aorta; LSCA, left subclavian artery. **B:** In this view of the same specimen, the large circular tube of conal septum (CS) has been cut through to show the aorta, the coronary artery (*small arrow*), and the papillary muscle of the conus (*small arrow*). Ao, aorta; MPA, main pulmonary artery; LAD, left anterior descending coronary artery. **C:** The conal septum has been moved toward the RV. In this view, note the VSD just inferior to the pulmonary artery. The papillary muscle of the conus can be seen attached to the malaligned conal septum. LAD, left anterior descending coronary artery; MPA, main pulmonary artery; Ao, aorta; CS, conal septum; VSD, ventricular septal defect. **D:** Left ventricular view demonstrates that the only egress from the left ventricle is through the VSD, which is immediately inferior to the pulmonary artery. Note proximity of the VSD to the cusps of the pulmonary valve (*small arrows*) as well as the fibrous continuity between the anterior leaflet of the mitral valve and the pulmonary valve cusps. MPA, main pulmonary artery; VSD, ventricular septal defect; MV, mitral valve; PV Cusp, cusp of pulmonary valve.

type,” “transposition type,” and “noncommitted type” by multiple surgical teams (41–45). Because of the complexity of the lesion and associated anomalies, various surgical procedures have been described over time. Due to the variety of procedures described, surgical planning must be applied to individual patients based on their specific cardiac anatomy.

Figure 51.7. Echocardiogram of DORV with noncommitted VSD. Subcostal coronal view demonstrates the VSD (arrows mark the crest of the interventricular septum and the tip of the conal septum), which is remote from both great arteries due to bilateral conus. VSD, ventricular septal defect; AO, aorta; PA, pulmonary artery.

ESSENTIAL DETERMINANTS OF SURGICAL CORRECTION AND TIMING OF THE OPERATION

It is not an exaggeration to state that surgical decision making for DORV is the most complicated in congenital heart surgery. Surgical decisions depend not only on specific anatomic features, but also on the patient’s age, body size, and clinical condition and the surgeon’s skill. Because each patient may be sufficiently unique to require an individual approach, repeated imaging with transthoracic or transesophageal echocardiography, angiography, computed tomography, or MRI may be required to obtain a precise anatomic roadmap. The relatively poor outcomes in the early years of surgery for DORV were due in part to the lack of precise anatomic definition and recognition of associated lesions.

Several anatomic features must be identified and defined well to allow for optimal surgical decision making (Table 51.1). The exact position, size, and number of VSDs are crucial to decide the type of repair. In addition, the relationship of the

TABLE 51.1

Essential Anatomic Determinants of Method of Surgical Repair of DORV

The position, size, and number of VSD(s) and its relationship to the conduction system
The distance between the tricuspid valve and the pulmonary valve
Straddling or overriding of the AV valve
Relationship of the great arteries
Presence of pulmonary (right ventricular outflow tract) stenosis
Presence of aortic (left ventricular outflow tract) stenosis
Coronary artery anatomy

TABLE 51.2 Usual Timing of Surgery for DORV

"VSD type": one-stage complete repair as a neonate or young infant because of pulmonary overcirculation
"Transposition type": one-stage complete repair as a neonate before the LV becomes unprepared
"Tetralogy type": one-stage repair within a few months of birth, or two stages with an initial palliative shunt followed by complete repair ≥ 6 mo of age
"Noncommitted type": complete biventricular repair is usually deferred beyond 6 mo of age because of the complexity of the baffle. Initial palliation with either an aortopulmonary shunt or pulmonary artery band may be needed.

conduction system to the VSD is important, because some VSDs must be enlarged to create a sufficient pathway for intracardiac baffling. The distance between the tricuspid valve and the pulmonary valve should be large enough to employ a LV-to-aorta baffle repair. If papillary muscle tissue is located in the pathway from the LV to aorta, relocation of the papillary muscle or valve replacement may need to be considered. An example of this situation would be straddling or severe overriding of the AV valve (46). If an adequate pathway cannot be achieved, a Fontan operation is required. In the current era, coronary artery anomalies are less challenging technically. However, the exact course of the coronary arteries is relevant to plan for coronary transfer and/or right ventriculotomy, if required.

The timing of the surgical intervention depends on the type of DORV and the specifics of the procedure (Table 51.2). In general, patients with "VSD type" DORV develop clinical signs of pulmonary overcirculation as young infants from an unrestricted VSD and usually require intracardiac repair. Patients with "transposition type" DORV develop progressive cyanosis and should undergo surgical repair as neonates while the LV remains prepared for systemic afterload. Patients with "tetralogy type" DORV show signs of cyanosis and require surgery in the first several months of life. However, because of the complexity of the intracardiac baffle and right ventricular outflow reconstruction, some surgeons opt for initial palliation with a systemic-to-pulmonary artery shunt and defer corrective surgery beyond 6 months of age. Patients with "noncommitted type" DORV often require complex intracardiac baffling. Because of the complexity of intracardiac repair, many surgeons prefer to defer corrective surgery and initially palliate those infants and young children who become symptomatic in the first 1 to 2 years of life. Lastly, for those whose anatomy precludes complex repair and a Fontan operation is the final palliation, an aortopulmonary shunt or pulmonary artery band is often selected as the initial technique to control pulmonary blood flow.

TYPES OF SURGERY AND SURGICAL STRATEGY

Historically, beginning with simple VSD closure in "VSD type" DORV, various surgeries have been proposed for the multiple forms of DORV (Table 51.3). These range from simple VSD closure to arterial switch to the highly complicated types of surgery such as aortic translocation (47). Some techniques are no longer employed because of poor outcomes, and others are not preferred because of the complexity of the procedure. In order to appreciate the strategic approach to surgical

TABLE 51.3 Possible Surgical Procedures for DORV

Palliation (banding or systemic-to-pulmonary shunt)
LV-to-aorta baffle closure (intracardiac rerouting)
Simple VSD closure (subaortic VSD type)
Patrick-McGoon
Kawashima (for original Taussig-Bing anomaly)
Intraventricular repair with RVOT reconstruction
Rastelli
REV (Lecompte)
Switch operation
Arterial switch operation (Jatene)
Atrial switch operation (Senning, Mustard)
Switch with RVOT reconstruction
Switch + Rastelli (or REV)
Aortic translocation (Nikaidoh, double root, truncal switch)
Single ventricle approach
Bidirectional Glenn shunt
Fontan operation
Biventricular repair with DKS
Yasui procedure

VSD, ventricular septal defect; RVOT, right ventricular outflow tract; DKS, Damus-Kaye-Stansel.

management of DORV, the following principles should be applied: (a) biventricular repair is performed if it is feasible, and (b) an adequate left ventricular outflow tract must be created, even if it compromises the right ventricular outflow (the right ventricular outflow tract can be reconstructed by infundibulectomy, valvotomy, gusset or conduit). The primary reason multiple surgical approaches have been proposed is that the left ventricular outflow tract must be created without obstruction in multiple anatomic variants. In addition, many variations have been proposed for surgical right ventricular outflow tract reconstruction.

In thinking of the surgical strategy for DORV, it is important to understand the patient's cardiovascular physiology. The surgical correction should also be a physiologic correction. For "VSD type" DORV, the purpose of the surgery physiologically is to eliminate the left-to-right shunt. This can be achieved by closing the VSD. In "transposition type" DORV, the ventricular outflows must be switched to achieve normal two-ventricle physiology. In "tetralogy type" DORV, routing blood from the LV to the aorta with enlargement of right ventricular outflow tract is required. After determining each patient's physiology, the anatomic features are identified to determine which surgical procedure is feasible (Figs. 51.9 and 51.10).

First, the sizes of the ventricles and AV valves should be measured. If the sizes of the ventricles and AV valves are adequate, a biventricular repair is planned. If the tricuspid valve or RV is small, a "one and one-half ventricle" repair can be selected. In this approach, the systemic and pulmonary circulations are fully separated, but the RV only pumps systemic venous blood from the inferior vena cava (IVC) to the lungs; blood from the SVC enters the lungs by a cavopulmonary anastomosis (typically a bidirectional Glenn shunt). Therefore,

Figure 51.9. Anatomical approach to the repair of the various anatomic subtypes of DORV. SV, single ventricle; PV, pulmonary valve; RVOT, right ventricular outflow tract; VSD, ventricular septal defects; DKS, Damus-Kaye-Stansel; RV-PA, right ventricle to pulmonary artery; IVR, intraventricular repair.

the RV is only required to pump IVC blood, since blood from the SVC is diverted directly into the pulmonary arteries.

Second, a determination must be made about whether a LV-to-aortic baffle can be created without creating any LV outflow tract obstruction. For this purpose, the distance between the tricuspid valve and pulmonary valve should be greater than normal. Some VSDs need to be enlarged, if possible, or the outlet septum should be resected. Some papillary muscles may need to be reattached. Most “VSD type” DORV patients can be repaired by simple patch closure of the VSD. In some cases of “transposition type,” this type of repair is also technically feasible and can be successful. Other approaches to “transposition type” DORV include the Patrick-McGoan procedure (if great vessel relationships are anterior-posterior or I-position with a large VSD) or a Kawashima procedure (Taussig-Bing anatomy with a large distance between the tricuspid valve and pulmonary valve) (41,42). Currently, however, because of the complexity of the intracardiac baffling techniques, an arterial switch operation is preferred, if possible (48,49). If right ventricular outflow reconstruction is required due to stenosis, a Rastelli procedure (right ventricle-to-pulmonary artery conduit) or REV procedure (Lecompte) is chosen (50,51).

Third, when a left ventricle-to-aortic baffle cannot be created, but a left ventricle-to-pulmonary valve pathway can be constructed without any stenosis, an arterial switch operation can be performed. In the past, an atrial switch operation with an intraventricular tunnel repair was used. However, this strategy has produced poor results in general, including hospital mortality rates as high as 30% to 40% (52,53). For this reason it is no longer employed. If there is any stenosis in the right ventricle-to-pulmonary artery route, a Rastelli conduit or REV procedure is added to the arterial switch. For this group of patients, and as an alternative to the arterial switch with right ventricular outflow tract reconstruction, more complicated approaches such as the Nikaidoh procedure (aortic translocation), double root translocation, or truncal switch operation were described (47,54,55).

If neither a LV-to-aortic valve nor a pulmonary valve pathway can be created without obstruction, a Damus-Kaye-Stansel (DKS) anastomosis with right ventricle-to-pulmonary artery conduit (Yasui procedure) for biventricular repair can be performed (56). Otherwise, conversion to a Fontan pathway is chosen. In some patients in whom straddling of the right or left AV valve complicates the anatomy of the VSD,

septation may not be possible without replacement of the straddling valve. Alternatively, if the pulmonary pressure and resistance are low, definitive palliation can be achieved in a stepwise fashion by an initial bidirectional Glenn shunt followed by a Fontan operation.

SURGICAL OUTCOMES

Mortality for repair of DORV depends on the anatomic variant and presence of any associated anomalies. Overall, early mortality for repair of DORV has been reported to range from 2% to 9%, and 15-year overall survival ranges from 56% to 90% in most recent large series (57–61).

In 1997, Kleinert et al. reported 193 DORV patients operated at Royal Children's Hospital in Melbourne from 1978 to 1993 (24). They divided patients into two groups. Patients in group 1 had AV concordance, a single VSD, balanced ventricle size, no straddling AV valve tissue, and no major pulmonary artery anomaly. Patients in group 2 were complex; they had multiple VSDs, straddling AV valve tissue, and ventricular hypoplasia. Of the 193 patients, 148 had a biventricular repair. Early mortality in group 1 was 3.6% versus 22% in group 2. Risk factors for mortality were multiple VSDs, operation before 1985, and aortic arch obstruction.

In 1999, Masuda et al. reported a series of 27 DORV patients with subpulmonary VSD (62). There was one operative death (3.7%) and three late deaths. The actuarial survival rate was 83% at 9 years. In 2001, Brown et al. reviewed 124 DORV patients from 1980 to 2000 (57). In this series, the early mortality was 4.8%; survival at 15 years was 95.8% for non-complex patients, 89.7% for subpulmonary VSD patients, and 89.5% for patients with straddling AV valve or hypoplastic ventricle.

In 2001, Takeuchi et al. reported the experience of patients with DORV and a subpulmonary VSD at Children's Hospital, Boston, from 1992 to 1999 (58). Of 34 total patients, 20 patients underwent an arterial switch operation and 12 underwent a bidirectional Glenn procedure followed by a modified Fontan. There were no deaths in the Glenn/Fontan group. Four patients in the arterial switch operation group died within 33 days of surgery. Actual survival at 5 years for the entire group was 87%.

Figure 51.10. A-C Surgical repair of the “VSD type” (A), “transposition type” (B), and “tetralogy type” (C) DORV. In each diagram, a cross section (superior to inferior) of the RV is shown along with the location of the VSD (*shaded oval*) and the position of the great arteries relative to the VSD. In the “transposition type” DORV diagram, the great arteries have been switched surgically (indicated by *suture lines* in each great artery).

In 2002, Lacour-Gayet et al. reported 10 patients with DORV with noncommitted VSD repaired by intracardiac rerouting to the pulmonary artery and arterial switch (63). At a mean follow-up of 20 months, there was one non-cardiac death, and all nine survivors had normal sinus rhythm and subaortic gradients <15 mm Hg.

In 2007, Bradley et al. published a review of 393 children with DORV at the Hospital for Sick Children in Toronto (64). These patients were classified as follows: subaortic VSD with or without pulmonary stenosis in 47%, subpulmonic VSD in 23%, noncommitted VSD in 26%, and doubly committed VSD in 4%. Biventricular repair was performed in 55% at a median age of 10 months, and a Fontan operation was performed in 23% at a median age of 3.7 years. Overall survival was 56% at 15 years. Interestingly, for complex DORV,

a Rastelli-type repair increased the early reintervention risk ($p = 0.04$) and late post-repair mortality ($p = 0.02$), whereas the arterial switch operation increased early post-repair mortality ($p = 0.02$) but improved late post-repair survival. They concluded that extending biventricular repair to borderline anatomic candidates who had hypoplastic left-sided structures or a non-subaortic VSD is a questionable strategy.

REINTERVENTION AND REOPERATION

In patients with simpler forms of DORV such as “VSD type” or “tetralogy type,” freedom from reoperation is excellent and comparable to the outcomes of patients with simple VSD and

tetralogy of Fallot (57,64,65). However, patients who undergo a Rastelli-type repair require one or more right-ventricle-to-pulmonary artery conduit replacements.

Patients with a complex intracardiac baffle are at substantial risk of left ventricular outflow tract obstruction. The risk of reoperation has been reported to vary from 5% to 50%, and this risk is particularly high in those with a subpulmonary VSD (66).

The survival of patients with “transposition type” DORV is now comparable to the outcomes of those with uncomplicated d-transposition of the great arteries (67). However, neo-aortic valve regurgitation in these patients is more common than in uncomplicated d-transposition of the great arteries, implying that they may need future aortic valve repair or replacement (67).

MANAGEMENT OF THE ADULT WITH DORV

The surgical treatment of DORV is so varied that the appropriate follow-up depends on multiple factors including the patient's condition, type of repair, and residual lesion(s), if any. The American College of Cardiology/American Heart Association (ACC/AHA) and Canadian Cardiovascular Society have published consensus guidelines for the management of adults with VSD, d-transposition of the great arteries, tetralogy of Fallot, and single ventricle with a Fontan operation individually, and these types of DORV patients should be managed according to the appropriate diagnosis-specific guidelines (68,69). All patients with DORV, whether they have undergone surgery or not, can benefit from regular follow-up with a cardiologist who has expertise and experience in the management of adults with congenital heart disease. Exercise intolerance and decline in functional status are important changes that should alert the cardiologist to the possibility of either a residual lesion or reduction in ventricular function. Patients with DORV, whether operated on or not, are at risk of both atrial and ventricular arrhythmias. Arrhythmia in these patients is typically caused by progressive, abnormal hemodynamics leading to chamber dilatation and/or hypertrophy with resultant ventricular dysfunction. Right bundle branch block and QRS prolongation after repair are common and may suggest an increased risk of sustained ventricular tachycardia and sudden cardiac death (70). These and other complications associated with DORV in adults are listed in Table 51.4.

Successful pregnancy and delivery after biventricular repair of DORV have been reported (71). When complications occur,

they are primarily non-cardiac, and the cardiac complications are less common and typically minor in comparison. However, infertility and menstrual cycle disorders appear to be more prevalent. Because of the lack of large studies with follow-up data on DORV patients, it seems reasonable to monitor pregnancy closely in “tetralogy type” patients with a subaortic VSD who underwent intracardiac biventricular repair. Generally, patients with a biventricular repair should have a low pregnancy risk, assuming good biventricular function, normal oxygen saturations, and absence of significant residual lesions causing hemodynamic effects (72,73). For patients with a Fontan palliation, successful pregnancy and delivery after a Fontan procedure for DORV have been reported (74).

Patients following DORV repair do not require routine endocarditis prophylaxis except in the following situations: prosthetic cardiac valve or device, previous endocarditis, for the first 6 months after intervention, and residual defect(s) at the site or adjacent to the site of a prosthetic patch or device (75).

NOMENCLATURE

Considerable controversy exists regarding the definition, classification, and nomenclature for various forms of complex congenital heart disease. As a result, the potential exists for confusion and misunderstanding both between and within institutions. This is especially true for the nomenclature of hearts with a large dominant ventricle and a small rudimentary ventricle. Terms that have been used to describe this group of hearts include single ventricle, univentricular heart, common ventricle and, more recently, single functional ventricle.

Van Praagh et al. (1) have emphasized that it is inaccurate to label hearts in this category as “single ventricle,” given that there are always two ventricular chambers present in mammalian hearts. In the late 1970s and early 1980s, Anderson et al. (2,3) attempted to clarify the classification of these hearts by introducing a new definition for what constitutes a ventricle. This definition was based on several important observations. First, normal ventricles possess an inlet, trabecular, and outlet portion. The inlet portion extends from the atrioventricular (AV) annulus to the insertions of the papillary muscles and does not require a perforate AV valve annulus. The trabecular portion exists between the inlet and outlet portions and includes the ventricular apex. Finally, the outlet portion of the ventricle includes the nontrabeculated region beneath a semilunar valve. The second observation that Anderson et al. based their definition on was that in the normal heart the inlet and outlet portions of the morphologic left ventricle (LV) are in fibrous continuity. But, in a morphologic right ventricle, the inlet and outlet portions are separated from one another by the crista supraventricularis. Their final observation that they based their definition of a ventricle on was that in the normal heart, each trabecular zone receives its own inlet. Based on these observations, Anderson et al. proposed that a chamber must have 50% or more of an inlet portion to be classified as a ventricle and need not have an outlet portion. Chambers receiving <50% of an inlet were defined as rudimentary chambers. Rudimentary chambers consisting of an outlet portion were classified further as an “outlet chamber.” Those possessing only a trabecular zone were called “trabecular pouches.” Based on these rules, Anderson et al. used the term univentricular heart of left ventricular type to describe hearts in which the dominant chamber was morphologically a LV and the rudimentary chamber had characteristics of the trabecular portion of a right ventricle. They used the term univentricular heart of the right ventricular type to describe hearts in which the dominant chamber was morphologically a right ventricle and the rudimentary chamber had the characteristics of the trabecular portion of a LV.

While their definitions have been accepted by many, other investigators believed these definitions were confusing, arguing that using the term “univentricular heart” is misleading because all hearts have two ventricular chambers. As result, in the late 1970s and early 1980s, many other authors continued

to describe these hearts based upon their abnormal AV connection, and preferred terms such as double inlet LV and tricuspid atresia. In 1984, in response to arguments against their definition of a ventricle, Anderson et al. (2) introduced the term “univentricular AV connection” to describe hearts in which both inlets (whether patent or not) were committed primarily to one dominant ventricle. In this system, the emphasis is on the use of the sequential segmental approach to define the dominant ventricular morphology present, the position and morphology of the rudimentary ventricle, the type of AV connection, and, finally, the position of the semilunar valves.

As discussed in some detail by Edwards and Maleszewski in Chapter 2, there are six possible AV connections. Two are biventricular (concordance and discordance), one is ambiguous (in cases of atrial isomerism), and three are univentricular (double inlet, single inlet, and common inlet). We prefer the definition of a ventricle as an endocardial-lined chamber within the ventricular mass, regardless of the ventricular components that are present or absent. The term “single functional ventricle” encompasses hearts with a small nonfunctional ventricle and includes hearts with univentricular AV connections, as well as those with an atretic semilunar valve and an intact ventricular septum (the hypoplastic left and right heart syndromes). Patients with any type of single functional ventricle are amenable to a modified Fontan type of surgical repair.

Throughout the remainder of this chapter we will use the sequential segmental approach to discuss conditions resulting in a univentricular AV connection (aortic or pulmonary atresia with an intact septum are discussed in two Chapters 41 and 48). For each condition, we will describe the dominant ventricular morphology as left or right, the type of AV connection, the position and morphology of the hypoplastic ventricle, and the spatial relationship of the great arteries. We will use the term “single functional ventricle” to help avoid any conceptual confusion that terms like “univentricular heart” and “single ventricle” might cause.

PATHOLOGIC ANATOMY

Ventricular Morphology

The most common form of univentricular AV connection is a double inlet LV with a hypoplastic right ventricle (1). In this anomaly, the rudimentary right ventricle is located anterior and superior to the dominant left ventricular chamber and most commonly connects to the ascending aorta (ventriculoarterial discordance). If the hypoplastic right ventricle lies along the right shoulder of the heart, the sidedness of the dominant LV will be normal, and if it is found on the left shoulder of the heart, then the left ventricular sidedness will be the mirror image (ventricular inversion or L-loop ventricles). In the dominant chamber, direct continuity between one or both AV valves and the semilunar valve establishes its morphology as

left ventricular. In short axis, the plane of the ventricular septum will be angled rather than perpendicular to the diaphragmatic ventricular wall and it will be displaced superiorly.

Double inlet right ventricle is an exceedingly rare anomaly. In this condition, the hypoplastic left ventricular chamber will be located along the inferior (diaphragmatic) aspect of the heart, usually to the right or left of midline. Only rarely will the hypoplastic chamber give rise to a great artery. Consequently, the ventriculoarterial connections are almost always right ventricular and may be double outlet, common outlet (truncus arteriosus), or single outlet (with pulmonary or aortic atresia). Demonstration of separation of the AV valves from the semilunar valves by a collar of myocardium (the conus, infundibulum, or outflow tract) will establish the morphology of the dominant chamber as right ventricular.

Rarely, the morphology of neither the dominant chamber nor the hypoplastic chamber can be determined with certainty. Such cases are typically categorized as single functional ventricle of undifferentiated or indeterminate type.

Atrioventricular Connections

A double inlet AV connection is almost always associated with a dominant morphologic LV. In this situation, both atria connect to the dominant ventricle by two distinct AV valves, which are usually mirror-image morphologic mitral valves, thus fulfilling the embryologic concept that AV valve morphology always corresponds to the morphology of the ventricle to which they connect (Fig. 52.1). When one of the valves straddles into the hypoplastic right ventricle, it will have a hybrid mitral–tricuspid morphology. In such hearts, the AV valves should be labeled as “right” and “left” rather than ambiguously as “mitral” and “mitral.”

In contrast, in hearts with a common inlet AV connection, the dominant ventricle is almost always of right ventricular morphology. It should be noted that common inlet right ventricle occurs much less frequently than double inlet LV (12% vs. 88%) (4).

The third form of univentricular AV connection is a single inlet ventricle, which includes tricuspid atresia and mitral atresia (discussed in detail in Chapters 38 and 48). These are characterized either by an imperforate valve orifice with a fibrous plug or by absence of the AV connection such that the corresponding atrium and ventricle are completely separated from one another (Fig. 52.2 and 52.3).

Annular, rather than cordal, features are used to determine AV connections. Overriding refers to partial commitment of an AV valve annulus to the contralateral ventricular chamber and results from malalignment of the atrial and ventricular septa.

Figure 52.2. Double inlet with single AV valve. Echocardiogram demonstrating an apical four-chamber view. There is DILV with atresia of the right AV valve. Note that the atretic right AV valve plate (arrow) is directed to the main ventricular chamber (MVC) of left ventricular morphology with malalignment of the atrial and ventricular septa. I, inferior; L, left; LA, left atrium; OC, outlet chamber of right ventricular morphology; PV, pulmonary vein; R, right; RA, right atrium; S, superior; SR, ventricular septal remnant. (From Seward JB, Tajik AJ, Hagler DJ, et al. *Two-dimensional echocardiographic Atlas*. Vol. 1. *Congenital Heart Disease*. New York, NY: Springer-Verlag, 1987:250, with permission.)

It can influence the determination of an AV connection. The percentage of annular commitment to a ventricular chamber relative to the position of the ventricular septum determines the AV connection to a ventricular chamber. In the setting of an overriding AV valve, an atrium is considered to connect to the ventricle into which 50% of its valve empties. Thus, an annular commitment of 50% or more to a ventricular

Figure 52.3. Angiographic, pathologic, and echocardiographic correlation in single-inlet LV. **A,B:** Anteroposterior and lateral views of a selective injection into the LV or main ventricular chamber (MVC) with absent right AV valve or tricuspid atresia. A hypoplastic right ventricular outlet chamber (OC) is observed anteriorly and supplies the pulmonary artery (PT). The great arteries are normally related, with the aorta (Ao) originating from the LV. **C,** catheter. **C,D:** Pathologic and echocardiographic comparison of findings observed in absent right AV valve. The specimen is cut similarly to the echocardiographic four-chamber view. The *small arrow* points to a tiny slit-like remnant of right ventricle. The main ventricular chamber (MVC) is the morphologic LV. The *arrowhead* points to the junction of the atrial and ventricular septa (VS), which are aligned. Only the left AV (mitral) valve (L) is committed to the LV. The right atrium (RA) is enlarged, and the atrial septum (AS) bulges into the left atrium (LA). MV, mitral valve.

chamber establishes the valve connection to that ventricular chamber (Fig. 52.4). If 75% or more of the annulus of a common AV valve empties into one ventricular chamber, then a common inlet ventricle pertains.

In contrast to annular overriding, straddling is a feature of the tendinous cords and papillary muscles and results from their insertions into the contralateral ventricle through a ventricular septal defect (VSD). In double inlet LV, an AV valve may straddle into the hypoplastic right ventricular chamber. The valve that straddles is almost always on the same side as the hypoplastic

outlet chamber. Thus, with a right-sided hypoplastic right ventricle, it is the right AV valve that may straddle. Figure 52.5 schematically depicts the progressive changes in AV connections that occur, linking double inlet connection to overriding connections to normal concordant connection. This may occur with either D-loop or L-loop ventricles. Straddling AV valves are often large and redundant and can develop appreciable regurgitation.

Occasionally, stenosis of an AV valve may be encountered. In a study by Shiraishi and Silverman (4), 30% of patients with a double inlet ventricle had at least mild stenosis of an AV

Figure 52.4. AV commitment. Schematic illustration of the determination of AV connection based on the 50% rule. Note the associated effect of increasing atrial and ventricular septal malalignment produced by increasing annular override. When the right AV annulus overrides >50%, there is a predominant right atrium (RA) to the LV connection. LA, left atrium, RV, right ventricle.

valve, most commonly the left-sided valve. Parachute mitral valve can also occur (Fig. 52.6).

Ventricular Arterial Connections

In univentricular heart, any ventriculoarterial connection can occur, including concordant connection (i.e., aorta arising

from morphologic LV), discordant connections (i.e., aorta arising off rudimentary outlet chamber with right ventricular morphology), double outlet from the dominant ventricular mass or from the hypoplastic rudimentary outlet chamber, and single outlet from the dominant ventricular mass. Similar to the normal two-ventricle heart, the ventriculoarterial relationship is defined by the ventricle from which most (>50%) of an overriding semilunar valve originates.

Figure 52.6. AV valve abnormalities. Echocardiogram demonstrating double-inlet right ventricle (RV) with severe stenosis of the left AV valve. There is a parachute-like deformity of the left AV valve with all the valve chordae committed to a single papillary muscle (P). The leaflets are also severely thickened (arrows). The left atrium (LA) is severely enlarged, consistent with severe left AV valve obstruction. A hypoplastic left ventricle (LV) is located posterior and to the left. I, inferior; R, right; S, superior; VS, ventricular septum.

Although many types of ventriculoarterial connections can occur in the setting of the univentricular heart, certain combinations are more common than others. In the setting of univentricular heart of left ventricular morphology, the majority of patients will have discordant ventriculoarterial connections, with the aorta arising from the rudimentary outlet chamber of right ventricular morphology, and the pulmonary artery arising from the dominant ventricular mass of left ventricular morphology. In the series by Shiraishi and Silverman (4), 86% of patients with univentricular LVs with a double inlet AV connection had transposition of the great arteries (4). Similar to the series published by Van Praagh et al. (1), the majority of patients in their series who had transposition of the great arteries also had L-looped ventricles (occurring in 63% of the patients). In this form, the aorta arises from the rudimentary outlet chamber of right ventricle morphology that is anterior, and leftward of the AV valves. The pulmonary artery arises from the morphologic LV. For the rest of the patients in their series, 23% were found to have transposition of the great arteries of the D-loop variety (i.e., aorta arising from outlet chamber of right ventricle morphology that sits anterior and rightward) and 14% of the patients had normally related great vessels (Holmes heart). Other common combinations described in the literature include the pattern seen with univentricular heart of right ventricular morphology. In this situation, the ventriculoarterial connection usually is double outlet from the dominant ventricular mass or is a single outlet with pulmonary atresia. In the univentricular heart of indeterminate morphology, there often is no outlet chamber and as result, there can only be a double outlet or a single outlet.

Pulmonary outflow tract obstruction frequently occurs with a univentricular heart. This can occur with either concordant

or discordant ventricular–arterial connections. When subpulmonary obstruction occurs, it typically is present within the ventricle of left ventricular morphology and is due to posterior deviation of the infundibular septum. Other causes of pulmonary outflow tract obstruction include anomalous attachments of the right AV valve or herniation of valvular tissue into the pulmonary outflow tract. In rare cases, there can be severe stenosis at the level of the pulmonary valve due to malformed leaflets or annulus hypoplasia.

Interventricular Communications

The connection between the dominant ventricular mass and the rudimentary hypoplastic outlet chamber has been referred to by several terms in the literature, including VSD, the bulboventricular foramen, and the outlet foramen. In double inlet LV, the defect will be in the muscular portion of the trabecular septum in most cases, separated from the semilunar valves and completely surrounded by muscle. However, when there is hypoplasia of the infundibulum, the defect may extend into the outlet septum to sit immediately underneath the semilunar valve (subaortic VSD). The outlet foramen often can be restrictive, occurring in 47% of cases in the series published by Bevilacqua et al. (5). The defect can be restrictive or unrestrictive at birth but often will become restrictive over time. In the series by Bevilacqua et al. (5), patients with double-inlet left ventricle (DILV) and transposed great arteries and pulmonary stenosis, the outlet foramen rarely was restrictive. However, when transposition of the great arteries was present without pulmonary stenosis, a restrictive outlet foramen was significantly more common.

COMMON FORMS OF SINGLE VENTRICLE

Double Inlet Left Ventricle

DILV is the most common form of single ventricle described in all series and represents the classically described form of single ventricle. It represents 78% of the cases reviewed by Van Praagh et al. (1). The Van Praagh classification also distinguished four subgroups of DILV based on the great artery relationships: I, normally related great arteries; II, right-anterior aorta; III, left-anterior aorta; and IV, left-posterior aorta (inverted). By combining the criteria distinguishing the types of DILV, three clinically observed forms occur (A-I, A-II, and A-III). In each of these clinical forms, other common associations include subaortic obstruction, pulmonary outflow tract obstruction, and conduction abnormalities (6).

Subaortic obstruction usually occurs with ventricular–great artery (VA) discordance and is located primarily at the VSD (bulboventricular foramen type). It also can be secondary to severe ventricular hypertrophy of muscle bundles within the hypoplastic right ventricle (Fig. 52.7). Subaortic obstruction occurs more often in patients with associated right AV valve atresia and in patients who have had previous pulmonary artery banding procedures. Pulmonary artery banding can set the stage for progressive ventricular hypertrophy and obstruction in patients who have naturally occurring mild restriction at the VSD. These patients often present in infancy with associated coarctation of the aorta.

Pulmonary outflow tract obstruction frequently occurs in DILV and may occur with either concordant or discordant VA connections. When subpulmonary obstruction occurs within the left ventricular chamber, it most frequently is due to posterior deviation of the infundibular septum. Alternatively, it may be due to anomalous attachments of the right AV valve or herniation of valvular tissue into the pulmonary outflow tract.

Figure 52.7. Subaortic obstruction. Pathologic specimen demonstrating the anatomic substrate of subaortic stenosis in double-inlet left ventricle (LV). There is severe stenosis of the VSD, or the embryologic bulboventricular foramen (arrow), communicating to the hypoplastic subaortic right ventricle (RV). There is secondary endocardial fibrosis at the site of obstruction. There is severe hypertrophy of the ventricular septum and the free walls of both RV and LV. A pulmonary artery (PA) band was present previously and has been removed. Ao, aorta; R, right atrioventricular valve; L, left atrioventricular valve.

Severe pulmonary valve stenosis and annular hypoplasia can occur. The valve is often bicuspid and thickened.

Conduction abnormalities similar to those described with AV and VA discordance (corrected transposition of the great arteries) can be present. When the AV connection is double inlet, the connecting AV node always is located anterolaterally at the acute margin of the right AV valve orifice (7,8). It subsequently perforates the annulus of the right AV valve to enter the main left ventricular chamber (Fig. 52.8). The nonbranching bundle courses along the right-sided rim of the VSD (outlet foramen) to reach the trabecular septum. The subsequent course of the bundle depends on the location of the rudimentary right ventricular chamber relative to the main ventricular chamber (MVC). If the hypoplastic right ventricle is right-sided, the right margin of the VSD is adjacent to the anterolateral node, and the nonbranching bundle passes

down directly onto the right rim of the VSD. The nonbranching bundle then descends toward the crest of the trabecular septum along the left ventricular aspect of the ventricular septum and branches beneath the septal crest. When the hypoplastic right ventricle is left-sided, the right rim of the VSD, which is now also the anterior margin of the defect, is separated from the anterolateral node by the posterior great artery. The nonbranching bundle therefore must run a more extensive course anterior to the posterior semilunar valve annulus to reach the trabecular septum (Fig. 52.8). In all instances, it is located on the left ventricular aspect of the trabecular septum and descends down the right rim of the ventricular septum, branching below the septal crest. Although the nonbranching bundle always maintains the same relationship to the right rim of the VSD, it appears to be in a different location with right- or left-sided hypoplastic right ventricle when viewed from the hypoplastic right ventricle. If the hypoplastic right ventricle is left-sided, the conduction tissue appears to run above the ventricular defect when viewed from the MVC. If the hypoplastic right ventricular chamber is right-sided, the conduction bundle appears to run beneath the VSD when viewed from the MVC.

DILV with Normally Related Great Arteries (A-I Single Ventricle, "Holmes Heart")

This form of DILV remains relatively rare, observed in only 15% of the Van Praagh series (7) (Fig. 52.9). Embryologically, the VSD providing communication between the main left ventricular chamber and the hypoplastic right ventricle represents the primitive bulboventricular foramen. Frequently, the VSD creates significant subpulmonary obstruction, resulting in a somewhat balanced circulation with some hypoxia and low pulmonary artery pressure.

DILV with Right-Sided Hypoplastic Subaortic Right Ventricle (A-II Single Ventricle)

DILV with right-sided hypoplastic subaortic right ventricle shares many anatomic features with a similar anomaly consisting of complete transposition of the great arteries with severe override and straddling of the right AV valve into the morphologic LV and associated hypoplasia of the morphologic right ventricle (Fig. 52.10). It was observed in 25% of the cases of single ventricle reviewed by Van Praagh et al. (9). The embryologic development of various types of DILV representing the extreme forms of AV valve straddling (Fig. 52.5) easily supports the common features shared by these defects. In some cases, the AV valve morphology also may follow this schema, with the left-sided AV valve having morphologic features of a mitral valve and the right AV valve features of a tricuspid valve. With VA discordance, the aorta also typically is right-anterior in location. Subaortic and pulmonary stenosis may occur. The conduction tissue enters the trabecular septum

Figure 52.8. Conduction tissue. Schematic illustration of the course of the nonbranching bundle of the conduction tissue along the right rim of the VSD in DILV. **A:** The findings in DILV with a left-anterior subaortic right ventricle. **B:** The conduction tissue in DILV with a right-anterior subaortic right ventricle. LAVV, left atrioventricular valve; RAVV, right atrioventricular valve. (From Davies MJ, Anderson RH, Becker AE. Atrioventricular conduction tissues in congenital heart disease. In: Davies MJ, Anderson RH, Becker AE, eds. *The Conduction System of the Heart*. London: Butterworths, 1983:137.)

Figure 52.9. Holmes heart. Pathologic specimen illustrating DILV with VA concordance and normally related great arteries. **A:** An external view demonstrating the opened hypoplastic right ventricle (RV), which gives off the pulmonary artery (PA). The aorta (Ao) is right posterior. **B:** Opened view of the LV, which receives both the right (R) and left (L) atrioventricular valves. The aorta originates entirely from the LV.

Figure 52.10. Ventricular myocardial morphology. **A:** Pathologic specimen demonstrating the typical left ventricular wall and fine myocardial trabeculations in the left ventricular (LV) chamber of DILV. There is also straddling (*small arrow*) of the right AV valve (R) into the hypoplastic right ventricle (RV). The *large arrow* indicates the stenotic pulmonary outflow tract. Subpulmonary stenosis is present because of posterior deviation of the conus septum the aorta [Ao] overrides the ventricular septum producing a tunnel-like fibromuscular stenosis. **B:** Pathologic specimen demonstrating typical right ventricular myocardial pattern of an irregular coarse ventricular wall with thick heavy trabeculations in the main chamber of common-inlet RV. The *white probe* enters the ventricle through a common atrioventricular valve. L, left atrioventricular valve.

Figure 52.11. Pathologic specimen of the most common form of DILV with left-sided hypoplastic subaortic right ventricle (RV) and left-anterior aorta (Ao) (A-III single ventricle). There is situs solitus of the atria and both right (R) and left (L) AV valves are entirely committed to the LV with no AV valve straddling. The VSD is well observed in the short-axis cut demonstrated in C. LA, left atrium; PA, pulmonary artery; RA, right atrium.

from an anterolateral node (7). The nonbranching bundle courses along the rightward rim of the VSD and subsequently distributes over the crest of the ventricular septum. Cook and Anderson reported an example of DILV with double-outlet LV and a small right-sided morphologic right ventricle which lacked both inlet and outlet components.

DILV with Left-Sided Subaortic Hypoplastic Right Ventricle (A-III Single Ventricle)

DILV with left-sided subaortic hypoplastic right ventricle is the most common type of univentricular connection observed in most reviews (9,10). It was encountered in 38% of the series review by Van Praagh et al. (9) In this early series, most examples of this defect were thought to represent examples of ventricular l-looping with the morphologic LV to the right and therefore with the morphologic mitral valve to the right of the morphologic tricuspid valve. Developmentally, one could speculate that this form of DILV shares anatomic features similar to AV and VA discordance (corrected transposition of the great arteries) but that severe overriding and straddling of the

left-sided tricuspid valve ultimately resulted in predominant commitment of the left AV valve to the morphologic LV and DILV (Fig. 52.11). Thus, varying degrees of residual straddling of the left AV valve into the morphologic right ventricle would not be an unusual finding in this form of DILV. This seems a plausible and rational developmental explanation; however, in many instances of DILV, the AV valve anatomy is not sufficiently distinct to allow accurate differentiation of morphologic mitral or tricuspid valves. There also is significant variation in the size of the morphologic right ventricular cavity. It may be extremely hypoplastic—a tiny slit-like chamber—or can be 75% or 80% of the size of a normal right ventricular chamber, particularly when the left AV valve straddles into the right ventricle.

A variety of associated AV valve, semilunar valve, and outflow tract anomalies may occur. Subaortic obstruction is an important associated lesion that must be assessed when considering a modified Fontan procedure. Significant ventricular hypertrophy substantially increases operative risk for Fontan operation because of associated ventricular diastolic filling abnormalities and elevated left ventricular end-diastolic pressure.

The conduction tissue abnormalities are similar to those described for AV and VA discordance (7). The AV node is anterolateral, and the nonbranching bundle courses into the ventricle anterior to the pulmonary outflow tract, subsequently coursing superiorly along the right (anterior) rim of the VSD. An ECG feature typically described for DILV is abnormal initial septal depolarization with the initial horizontal plane QRS vector directed leftward and anteriorly rather than rightward. There is an absence of a precordial Q wave. This abnormal septal depolarization is secondary to the abnormal course of the conduction system as previously described and in patients with AV and VA discordance.

Double-Inlet Right Ventricle

Double-inlet right ventricle was found in only two patients, or 5%, of the series reviewed by Van Praagh et al. (1,9). These investigators described it as an absence of the left ventricular sinus. There was a virtual absence of the LV, however. The ventricular myocardium had coarse, straight trabeculations consistent with right ventricular morphology. However, investigators in more recent reviews (6) noted the presence of a hypoplastic rudimentary left ventricular chamber that usually can be recognized by careful angiographic or echocardiographic analysis. Both AV valves either have >75% of the total AV valve orifices or complete connection to the morphologic right ventricle. The hypoplastic LV usually is located posteriorly and slightly to the left of the morphologic right ventricle. This ventricular relationship is consistent with an embryologic D-ventricular loop. Less often, the ventricular relationships are inverted, with the hypoplastic LV anterior and to the right, consistent with an L-ventricular loop. There is considerable variability in the size of the hypoplastic left ventricular chamber, but most often it is very hypoplastic. The VA connections may be concordant or discordant, but double-outlet right ventricle is usually present. Frequently, pulmonary stenosis or atresia is present with infundibular and pulmonary annular hypoplasia. If there is significant straddling of the AV valve, the LV may be large.

The path of the conduction tissue is related to the location of the hypoplastic LV and is normal when the hypoplastic LV is leftward and posterior (7). With the ventricular relationships inverted, the pattern is typical of that observed with AV and VA discordance (congenitally corrected transposition of the great arteries). Essed et al. (11) reported a sling of conduction tissue between a regularly positioned posterior node and a typical anterolateral node in AV and VA discordance.

Double-Inlet Ventricle of Mixed Morphology

Double-inlet ventricle of mixed morphology is a rare form of univentricular connection and occurred in only 5% of the series reported by Van Praagh et al. (1,9). Also called a common ventricle, it was designated by Van Praagh as the C type of single ventricle with absence of the ventricular septum or undivided ventricles with a rudimentary septum. A small apical ridge of ventricular septum may often separate the right and left ventricular zones of the heart. Relationships of the ventricular zones are usually consistent with normal ventricular locations or D-ventricular looping. Often, the great arteries are normally related; however, malposition with right- or left anterior aorta may occur. Subvalvular and valvular pulmonary stenosis may be present.

The conduction system has been described as normal, with a regular posterior position for the AV node (7). In some, there may be dual AV nodes with a sling of conduction tissue connecting the two. The nonbranching bundle appears to descend into the remnant of ventricular septum that separates the right and left ventricular zones.

Double-Inlet Ventricle with Indeterminate or Undifferentiated Morphology

This often is considered a primitive form of univentricular AV connection without a rudimentary chamber. It shares many of the pathologic features of both double-inlet right ventricle and double-inlet of mixed morphology (Fig. 52.12). This type

Figure 52.12. Double-inlet ventricle (mixed and indeterminate). The pathologic descriptions of these forms of double-inlet ventricle often share similar features. **A:** Pathologic features of mixed or indeterminate ventricular morphology with coarse trabeculated myocardium on the right and smooth-walled myocardium on the left. **B:** Pathologic specimen demonstrating double-inlet ventricle (V) of indeterminate morphology. Some features of this specimen suggest DILV but with left ventricular noncompaction. The right (R) and left (L) AV valve chordae interdigitate into the same papillary muscles within the same ventricle. Only the aorta (Ao) originated from the ventricular chamber.

of double-inlet ventricle often is diagnosed when no clear-cut differentiation or distinction of ventricular myocardium can be determined. AV valve abnormalities can include valvular stenosis or hypoplasia. Large, malformed AV valves often are regurgitant. The great arteries may be normally related. However, most commonly, the aorta is located anteriorly and to the right or left of the pulmonary artery. Pulmonary stenosis with subvalvular and valvular stenosis or pulmonary atresia may be present.

Location of the conduction system varies, with anterolateral and normally positioned posterior nodes described (7). The nonbranching bundle either penetrates directly into the right lateral wall of the ventricular chamber or descends through a large trabeculation toward the ventricular apex.

Single-Inlet Ventricle

This can include all forms of univentricular AV connection resulting from atresia or absence of either the right or left AV valve. The single-inlet connection may be to either a morphologic right ventricle with mitral valve atresia or a morphologic LV with tricuspid valve atresia. AV concordance is common, but the AV connection can be discordant. Either ventricle can be hypoplastic. Figure 52.3 illustrates a pathologic, angiographic, and echocardiographic correlation of single-inlet LV with right AV valve (tricuspid) atresia. VA concordance or discordance occurs with a range of great artery relationships from normal

to transposition with a right or left anterior aorta. Subvalvular and valvular pulmonary stenosis can occur with concordant or discordant VA connections. Subaortic obstruction may occur predominantly with discordant VA connections.

When there is AV concordance with absent right AV connection or classic tricuspid atresia, the conduction system is similar to that seen in isolated VSD (12). As viewed from the hypoplastic right ventricle, the nonbranching bundle is located on the left ventricular aspect of the right rim of the VSD, unrelated to the septal crest. With AV discordance, the regular posterior node cannot make contact with the ventricular myocardium. Instead, the anterior AV node is the connecting node, and the nonbranching bundle encircles the anterior aspect of the pulmonary valve to reach the right rim of the VSD where the bundle branches. With single-inlet right ventricle, the nonbranching bundle on the ventricular septum makes contact with the normally located posterior AV node. In some cases, the conduction tissues may descend through a large, free-running trabeculation to the ventricular apex.

Common-Inlet Ventricle

Common-inlet ventricle is a unique form of univentricular AV connection that is characterized by communication of both atria to a single-ventricular chamber by a common AV valve. It is a form of AV septal defect. Frequently, this is associated with situs ambiguus, particularly asplenia (Fig. 52.13). In the

Figure 52.13. Common-inlet AV connections. **A:** Pathologic specimens illustrating features of common atrium and common-inlet right ventricle (RV). **A,** 2-day-old infant with situs ambiguus, levocardia, and asplenia (right isomerism). There is a common atrium (CA) and common-inlet RV. With the opened view of the RV, the white arrows outline the common inlet. The atretic pulmonary outflow tract (*black arrow*) is to the right and slightly posterior to the aorta (Ao). There is no evidence of a LV. **B:** Common-inlet RV in a 14-year-old with levocardia and polysplenia (left isomerism). The hepatic veins (HV) entered the floor of the left side of the common atrium (CA) while the pulmonary veins entered the ipsilateral side of the atrium. A tiny slit-like left ventricle (LV) does not receive inflow from the common AV valve. **C:** Common-inlet RV in a 7-year-old patient with right isomerism. The common AV valve is nearly entirely committed to the large morphologic RV. There is an L ventricular loop with a small right-sided morphologic LV (probe), which receives a few cords of the AV valve.

common-ventricle series of Van Praagh et al. (1,9), about 33% had a common AV inlet, with 40% of these having asplenia. As with unbalanced AV septal defects, the main or larger ventricular chamber, depending on the predominant commitment of the common AV valve, may be a morphologic LV (type A Van Praagh), a morphologic right ventricle (type B), or a ventricle with undifferentiated myocardium (type D). There often is double-outlet right ventricle or VA discordance with a right or left anterior aorta, but normally related great arteries also have been reported. Stenosis or atresia of the pulmonary valve is frequent. In hearts with MVC of left ventricular type, the right ventricular portion of the common AV valve may be stenotic or partially atretic, resulting in predominant commitment of the common AV valve to the morphologic LV. Similarly, stenosis or atresia of the left component of the common AV valve may occur with a predominant right AV component and morphologic right ventricle. Because of the common drainage of both atria through a common AV orifice, the stenotic or atretic portion of the AV valve does not seem to disqualify such cases from the category of common AV connection. The disposition of the AV conduction tissue seems determined primarily by the anatomic relationships observed in AV septal defects. Often, both posterior and anterolateral node structures give rise to the penetrating bundles and a sling of conduction tissue. With indeterminate or morphologic right ventricular morphology, the penetrating bundles are described as descending along the posterolateral aspect of the MVC. Some hearts with 1-loop ventricular relationships have been described as having predominant or single anterolateral node with the penetrating bundle having a relationship to the ventricular septum typical of that observed with corrected transposition of the great arteries.

Clinical Features

The clinical features of univentricular AV connection are determined primarily by the presence or absence of pulmonary outflow obstruction. Patients without obstruction to pulmonary blood flow will demonstrate signs and symptoms typical of other large, left-to-right shunting VSDs. Severe congestive heart failure with tachypnea, tachycardia, diaphoresis, hepatomegaly, and failure to thrive may manifest within the first 3 months of life. Symptoms of congestive heart failure earlier in the neonatal period will more often be secondary to associated lesions such as AV valve abnormalities, aortic outflow obstruction, and coarctation of the aorta. Because of increased pulmonary blood flow, cyanosis may not be evident. Some patients with DILV and subaortic right ventricle to the left (inverted) have “favorable streaming,” with systemic venous blood preferentially directed into the pulmonary artery and pulmonary venous return directed to the aorta. Similarly, patients with right-sided subaortic right ventricle and various degrees of straddling right AV valve may have “unfavorable” streaming with transposition-like blood flow patterns resulting in significant systemic hypoxemia and cyanosis. A soft systolic ejection murmur secondary to flow-related relative pulmonary outflow obstruction or flow through the VSD to the hypoplastic right ventricle may be heard. Because of the presence of large pulmonary blood flow, a diastolic AV valve inflow murmur may be present. Pulmonary congestion and pneumonia can be the presenting findings.

If moderate pulmonary outflow obstruction or atresia is present, hypoxemia and cyanosis may be observed during the neonatal period. A systolic thrill may be present with pulmonary or subaortic outflow obstruction. A systolic ejection murmur and single second heart sound may be heard. The pulmonary valve closure sound may be audible and have mild degrees of pulmonary obstruction. No murmur may be

audible, or a soft continuous murmur may be evident secondary to a patent ductus arteriosus or a systemic pulmonary collateral artery with pulmonary atresia. In older patients with long-standing pulmonary hypertension, severe pulmonary vascular obstructive disease may be present by 2 years of age, resulting in progressive reduction in pulmonary blood flow and cyanosis. The second heart sound may be single and accentuated. A diastolic murmur of pulmonary valve regurgitation may be present.

Echocardiographic Features

Diagnostic features of univentricular AV connection are best detailed from the apical view delineating the crux of the heart, as in the apical four-chamber view, demonstrating the AV connection and the status and commitment of the AV valves (13–15). Figure 52.14 demonstrates the echocardiographic apical view in the basic type of univentricular connection, including double-inlet ventricle, single-inlet ventricle, and common-inlet ventricle. Additionally, parasternal short-axis scans and subcostal four-chamber views are particularly important for detailing the location of papillary muscle and chordal attachments within the ventricular chambers, the location of hypoplastic outlet or rudimentary chambers, the status of the AV valve leaflets and orifice sizes to assess for valvular stenosis, and for illustrating the location, commitment, and relationships of the great arteries. Figure 52.15 illustrates progressive short-axis scans in a patient with DILV with hypoplastic subaortic right ventricle anterior and to the left. At the apex (Fig. 52.15A), a large MVC of left ventricular morphology is observed posteriorly. As the scan progresses to the base, both AV valves are committed nearly entirely to the LV, and a single chordae of the left AV valve attaches near the VSD in the hypoplastic right ventricular outlet chamber. At the base of the heart (Fig. 52.15D), the aorta is anterior and to the left. There is evidence of severe pulmonary valve stenosis with a thickened bicuspid pulmonary valve. Short-axis scans demonstrate the ventricular chamber dimensions and wall thickness and provide a visual estimate of global ventricular contractility. Figure 52.16 illustrates parasternal short- and long-axis scans in a patient with DILV and hypoplastic subaortic right ventricle. Both the short- and long-axis scans allow estimation of the size of the VSD, which is relatively obstructive. There also is hypertrophy of the ventricular septum, producing additional right ventricular outflow obstruction. A tight pulmonary artery band that produces severe main pulmonary artery obstruction is seen. Subaortic obstruction has been observed frequently in patients with DILV following pulmonary artery banding and Fontan operation (16). It remains uncertain whether pulmonary artery banding simply provokes progressive ventricular hypertrophy in a patient with an underlying substrate of mild subaortic obstruction or whether the development of subaortic obstruction occurs *de novo* in a patient with no previous evidence of aortic obstruction.

Continuous-wave Doppler interrogation of the ascending aorta from a high left parasternal location (near the second intercostal space in the midclavicular line) provides an estimate of the subaortic obstruction by determining the mean subaortic gradient by planimetry of the ascending aortic velocity tracing to obtain a mean velocity and applying the Bernoulli equation ($\text{pressure gradient} = 4V^2$). A mean gradient estimate of the subaortic obstruction is used because the maximum instantaneous gradient overestimates the catheter-measured peak-to-peak systolic gradient (17). If significant subaortic obstruction is observed, there may be concomitant hypoplasia of the aortic annulus and ascending aorta with associated coarctation of the aorta. Adequate parasternal and suprasternal notch imaging must be obtained to assess the

Figure 52.14. Univentricular AV connections. Two-dimensional echocardiographic apical four-chamber views demonstrating (A) double-inlet, (B) single-inlet, and (C) common-inlet connections. In (B), the arrowhead points out the AV junction. There is no malalignment of the atrial and ventricular septa. There is only the left AV valve committed to the main ventricular chamber (MVC). In (C), there is a common inlet with a common AV valve (CAVV) draining both right and left atria. AS, atrial septum; L, left atrioventricular valve; LA, left atrium; PV, pulmonary vein; R, right atrioventricular valve; RA, right atrium.

status of the aorta and aortic arch. Figure 52.17 illustrates parasternal short-axis scans of two examples of double-inlet right ventricle with posterior rudimentary left ventricular chambers. Ventricular morphology can be assessed from similar parasternal short-axis scans, demonstrating the AV valve leaflet configuration (trileaflet vs. bileaflet) and the papillary muscle arrangement (multiple vs. double). Ventricular myocardial morphology suggested by a coarse trabecular ventricular wall pattern or smooth wall appearance is illustrated with short-axis scans of Figure 52.18, demonstrating double-inlet ventricle of mixed morphology. The anatomy is suggestive of the type C common ventricle of Van Praagh et al. (1,9) or an undivided ventricle with right ventricular morphology on the right and left ventricular morphology on the left.

Apical and subcostal four-chamber views should be used to demonstrate AV valvular abnormalities, including atresia or stenosis, and annular override or valvular straddling. Figure 52.19 illustrates an apical view in a patient with DILV and overriding and straddling right AV valve. There is >50% commitment of the right AV valve into the LV, establishing the diagnosis of DILV; however, the right AV valve also has some commitment and chordal attachment into the morphologic right ventricle. This observation is similar to the schematic drawings proposing the embryologic development of double-inlet ventricle from a progressively increasing degree of

AV valve override. The apical four-chamber view of Figure 52.2 illustrates an example of DILV with right AV valve atresia. The AV septum is shifted to the left, resulting in primary commitment of the atretic plate of the right AV valve into the morphologic LV and establishing the diagnosis of DILV. A small subpulmonary right ventricular outlet chamber is observed on the right. The apical view allows assessment of the planes of the atrial and ventricular septa, determining the degree of atrial commitment to a ventricular chamber. When combined with Doppler echocardiography and color-flow imaging, an estimate of severity of AV valve stenosis or regurgitation can be made. Subcostal views may be used to illustrate the status of the AV connection (double, single, common) and to obtain parasagittal or long-axis views to demonstrate the aortic and pulmonary outflow tracts. The four-chamber view illustrated in Figure 52.6 demonstrates an example of double-inlet right ventricle with severe stenosis of the left AV valve. There is marked thickening of the valve leaflets with short, thickened chordae to a papillary muscle in the right ventricle. The left atrium is enlarged, consistent with left AV valve obstruction. A hypoplastic, rudimentary left ventricular chamber also is observed to the left of the large right ventricle. Figure 52.20 illustrates a pathologic specimen and an echocardiographic subcostal view demonstrating single-inlet right ventricle with left AV valve atresia. Atretic valve tissue forms a dense plate at

Figure 52.15. Progressive parasternal short-axis scans from apex (A) to base (D) in a patient with DILV with left-anterior subaortic right ventricle. There is a large VSD (white arrow) from the main ventricular chamber (MVC) of the left ventricular morphology into the hypoplastic outlet chamber (OC) of right ventricular morphology. The left (L) AV valve straddles into the right ventricular chamber through the VSD. There is pulmonary valve (PV) stenosis with thickened leaflets (black arrows). Ao, aorta; LA, left atrium; PA, pulmonary artery; R, right atrioventricular valve; RA, right atrium; VS, ventricular septum.

Figure 52.16. Parasternal short-axis (left panel) and long-axis (right panel) scans in a patient with DILV with previously placed pulmonary artery (PA) band. The VSD (arrows) is a moderately restrictive communication between the main ventricular chamber (MVC) and the outlet chamber (OC) of right ventricular morphology. In addition, the ventricular septum (VS) is moderately hypertrophied. Ao, aorta; L, left atrioventricular valve; LA, left atrium; R, right atrioventricular valve; RA, right atrium; VS, ventricular septum. (From Seward JB, Tajik AJ, Hagler DJ, et al. Two-dimensional echocardiographic Atlas. *Congenital Heart Disease*. Vol. 1. New York: Springer-Verlag, 1987:240, with permission.)

Figure 52.17. Parasternal short-axis scans demonstrating two examples of double-inlet right ventricle with a posterior hypoplastic LV. A: Hypoplastic LV (white P) posterior and to the right. B: Hypoplastic LV (P) posterior and to the left. The right-sided hypoplastic LV suggests that L-ventricular looping occurred, and the LV suggests a D-ventricular loop. In both cases, the AV valves were entirely committed to the main ventricular chamber (CV and MVC). L, left atrioventricular valve; black p, papillary muscle; PW, posterior wall; VS, ventricular septum.

Figure 52.18. Progressive parasternal short-axis scans (A–C) from apex to mid-ventricle demonstrate features of double-inlet ventricle of mixed ventricular morphology. Typical echocardiographic features for right ventricular morphology with coarse and dense myocardial trabeculations are observed on the right side of the main ventricular chamber (MVC); a smooth wall appearance and two papillary (P) muscles are noted on the left. At mid-ventricle, the right (R) AV valve has a triangular shape (trileaflet), and the left (L) has an oval (bileaflet) shape. There is no evidence of a ventricular septal ridge or remnant.

Figure 52.19. Apical four-chamber view demonstrating double-inlet LV with straddling right AV valve. More than 50% of the right AV valve annulus is committed to the left-sided morphologic LV. Arrows point to abutting leaflet of the right and left AV valves. LA, left atrium; RA, right atrium; RV, right ventricle; VS, ventricular septum.

the expected site of the mitral valve. A hypoplastic rudimentary LV is observed inferior to the atretic valve tissue. Both great arteries arise from the morphologic right ventricle.

Radiographic Features

Several typical radiographic findings may be observed in patients with double inlet with hypoplastic subaortic right ventricle located anteriorly and to the left (18). As in AV and VA discordance (corrected transposition), the posteroanterior chest film demonstrates a prominent upper left-sided heart border consisting of the right ventricular infundibulum, the aortic root, and the ascending aorta (Fig. 52.21). The main pulmonary artery and the right pulmonary artery may be dilated and can produce a prominent upper right-sided heart border and right pulmonary hilum described as a waterfall right hilum.

In cases with a moderate degree of pulmonary stenosis, the pulmonary vascularity may appear normal or slightly decreased. The heart size may be normal or only mildly enlarged. With pulmonary atresia, the pulmonary vascularity may be reduced or asymmetric as a result of systemic-to-pulmonary artery shunting.

Magnetic resonance imaging (MRI) is extremely valuable for demonstration of extracardiac abnormalities of systemic and pulmonary venous connections and aortic arch and central and proximal pulmonary artery branch abnormalities. When used in combination with coronal images, MRI has been an effective means of establishing segmental descriptions of congenital cardiovascular anomalies, including viscerotransposition and types of AV and VA connections. ECG-gated transverse images should provide an excellent means of accurate assessment of ventricular mass, similar to techniques described for cine computed tomography (CT) studies. Recognition of the impact of increased ventricular mass on surgical mortality and morbidity has been described in several studies that investigated the development of subaortic stenosis in patients with

double-inlet ventricle both before and after surgical repair by the modified Fontan procedure (16,19). Recent studies demonstrated that MRI provides an excellent noninvasive method for preoperative assessment of ventricular mass, volume, and function for the irregularly shaped ventricular chambers observed in the various types of univentricular AV connection.

Cardiac Catheterization and Angiography

The goals of cardiac catheterization should include a demonstration of (a) the location and integrity of systemic and pulmonary venous connections, including the presence and adequacy of atrial communications; (b) the status and function of AV and VA connections and valves; (c) basic ventricular morphology and function, including chamber dimensions, hypertrophy, and systolic and diastolic function; (d) the size, integrity, distribution, and arteriolar resistance of the pulmonary vascular bed; and (e) the location and integrity of the aorta and aortic arch to exclude coarctation and to assess presence of systemic-pulmonary arterial collaterals or shunts.

Venous Connections

An assessment of the systemic venous connections should include demonstration of hepatic and inferior vena caval connections either by echocardiography or angiography. Also, angiographic demonstration of the innominate vein should establish its drainage through the right superior vena cava and exclude the presence of a persistent left superior vena cava. If a left superior vena cava is present, its size and connection either to the right or left atrium should be determined. If surgical ligation of a persistent left superior vena cava is considered, balloon occlusion of each superior vena cava with an end-hole balloon-tipped catheter should be used to determine the rise in venous pressure distal to the balloon. An increase in superior vena caval pressure to >20 mm Hg suggests inadequate collateral venous communications to allow safe ligation of the superior vena cava. The presence and integrity of pulmonary venous connections should be determined either by direct catheter measurement of pulmonary venous pressure and pulmonary venous angiography or by pulmonary arterial angiography and pulmonary venous wedge pressure measurement. Anomalous pulmonary venous connections and pulmonary venous stenoses should be excluded. If a single-inlet or an atretic AV connection is present, the presence and adequacy of an interatrial communication should be assessed by echocardiography and Doppler color-flow imaging and by direct catheter measurement of the interatrial pressure gradient. If obstructed systemic or pulmonary venous drainage is determined, atrial septostomy should be performed.

Atrioventricular and Ventricular-Great Artery Connections

Two-dimensional (2-D) echocardiography provides excellent demonstration of the status of the AV connections; however, cineangiography also provides clear demonstration of AV valve commitment, annulus size, and leaflet abnormalities as well as reliable assessment of the presence and severity of valvular regurgitation. Severe AV valvular regurgitation results in ventricular volume overload and elevated filling pressures. Preoperative recognition of these abnormal hemodynamic states is mandatory for accurate assessment of the potential benefits, morbidity, and mortality of the modified Fontan procedure compared with staged palliative procedures (19,20). An initial ventriculogram using standard anteroposterior (AP) and lateral projections provides excellent demonstration of the AV valves and function. As with echocardiography, better demonstration of AV valve commitment and annulus size is obtained from a four-chamber view. The standard AP and lateral views

Figure 52.20. Subcostal 2-D echocardiogram demonstrating features of single-inlet right ventricle with left atrioventricular (mitral) valve atresia. **A:** The scan also demonstrates a dense echo (*arrowheads*) at the anticipated site of the atretic mitral valve overlying a small muscular chamber suggestive of the LV. The atrial and ventricular septa are aligned, and only the tricuspid valve (TV) is committed to the right ventricle. **B:** Pathologic specimen cut to conform to the subcostal echo view also demonstrates a single-inlet right ventricle. *Arrowheads* point to the anticipated site of the mitral valve, which is absent. **C:** The same specimen cut in a long-axis plane to demonstrate the main right ventricular chamber and a slit-like hypoplastic posterior LV (*arrowhead*). LA, left atrium; RA, right atrium; RV, right ventricle. (A: From Seward JB, Tajik AJ, Hagler DJ, et al. Two-dimensional echocardiographic Atlas. *Congenital Heart Disease*. Vol. 1. New York, NY: Springer-Verlag, 1987:240, with permission.)

of the ventriculogram generally provide an excellent demonstration of the VA connections and great artery relationships. Figure 52.22 demonstrates AP and lateral views in three types of DILV with anterior hypoplastic right ventricular outlet chamber. These views demonstrate examples of VA concordance, VA discordance, and double-outlet chamber connections. In most cases of DILV, the AP view provides clear demonstration of the size and adequacy of the VSD and the presence of subaortic obstruction at the VSD or within the hypoplastic right ventricle (Fig. 52.23). With angiographic or echocardiographic evidence of subaortic obstruction or a restrictive VSD, careful catheter measurement of aortic and ventricular pressures should be obtained to assess the presence and severity of subaortic obstruction. Simultaneous pressure recordings from the LV and aorta provide accurate measurements of the subaortic gradient. Isoproterenol infusion with simultaneous catheter measurement of left ventricular and aortic pressures also has been recommended to unmask mild or potential subaortic obstruction in the absence of a resting significant pressure gradient (16,21). Resting subaortic pressure gradients of

40 mm Hg or greater have been associated with high operative mortality for the modified Fontan procedure (19). Aortic valve regurgitation usually is demonstrated by 2-D Doppler color-flow imaging; however, in the presence of severe regurgitation, aortic root angiography is necessary to assess the severity of valvular regurgitation prior to aortic valve replacement.

Ventricular Morphology and Function

The basic intracardiac anatomy and ventricular morphology usually can be determined using standard AP and lateral projections by selective injection into the MVC. Figure 52.23 illustrates AP and lateral views of three types of double-inlet ventricle. Double-inlet ventricles of left, right, and indeterminate morphology are demonstrated. Rudimentary hypoplastic right and left ventricular chambers also can be recognized in the same views. Some investigators prefer axial cineangiography to demonstrate the ventricular anatomy. An AP projection of double-inlet ventricle with mixed morphology is demonstrated in Figure 52.24. In this example, the morphologic right

Figure 52.21. Anteroposterior left ventricular angiogram demonstrating the cardiac structures making up typical cardiac shape or contour observed in DILV with left-anterior aorta. Arrows point out the descending right lower lobe pulmonary artery described as producing a waterfall right hilum appearance. Ao, aorta; LV, left ventricle; RPA, right pulmonary artery; RV, right ventricle.

ventricle is located on the left, and there is a double-outlet right ventricle. Despite the irregular ventricular shape, estimates of ventricular ejection fraction obtained from ventricular volume calculations provide a global assessment of systolic ventricular function. Both 2-D and 3-D echocardiography can provide reliable assessments of ventricular volume, mass, and systolic function. Recent comparisons of 3-D echocardiography and MRI images in univentricular AV connection demonstrated similar results.

Ventricular diastolic function may be assessed by 2-D and Doppler echocardiography by assessing pulmonary venous and AV inflow patterns. Findings associated with restrictive disease and ventricular hypertrophy have been described. Further assessment in the cardiac catheterization laboratory can be achieved by measuring ventricular end-diastolic volume, ventricular mass, and estimates of ventricular mass to end-diastolic volume ratio, with concomitant measurement of atrial filling pressures and ventricular end-diastolic pressures. Mean atrial pressures and ventricular end-diastolic pressures exceeding 14 mm Hg may reflect ventricular volume load states, decreased ventricular compliance, or intermediate combinations of both hemodynamic conditions. Elevated filling pressures obligatorily result in elevated mean pulmonary artery pressures, but pulmonary arteriolar vascular resistance determinations also depend on pulmonary flow volume. Several groups demonstrated successful Fontan repairs in patients who did not meet the selection criteria originally proposed by Choussat et al. (22).

Pulmonary Circulation

Adequate pulmonary artery size and distribution have been considered critical components in planning palliative surgical procedures as well as in predicting successful definitive surgical repair, such as modified Fontan procedure. Adequate demonstration of the pulmonary arterial system to delineate the central pulmonary artery size and to exclude distortion or stenoses of the central pulmonary arteries and the distal

Figure 52.22. Anteroposterior and lateral views of selective left ventricular angiography in DILV demonstrating three types of great artery relationships. **Top panel (A-I)** illustrates ventricular-great artery (VA) concordance with normally related great arteries. **Middle panel (A-III)** illustrates VA discordance with left-anterior aorta. In addition, an aortic arch anomaly with coarctation is present. The subaortic area and the VSD are mildly stenotic. After a Fontan operation, the subaortic stenosis increased requiring further intervention. **Bottom panel (DORV)** illustrates a double-outlet "outlet chamber," or double-outlet right ventricle.

pulmonary arterial distribution remains a critical component of a complete preoperative assessment. This requires special efforts to obtain selective pulmonary artery injections in AP and lateral projections and, if necessary, using cranially angulated right and left oblique views to delineate the central and distal pulmonary arteries. Nakata et al. (12) proposed a method for quantitative standardization of pulmonary artery cross-sectional areas. They determined a normal pulmonary artery area index of $330 \text{ mm}^2/\text{m}^2$. Girod et al. (23), however, observed Fontan survivors with pulmonary artery cross-sectional areas as low as $188 \text{ mm}^2/\text{m}^2$. Previously placed surgical systemic-to-pulmonary artery shunts and Glenn-type cavopulmonary artery shunts must be demonstrated angiographically to exclude pulmonary artery distortion or stenosis.

Pulmonary arteriovenous fistulae are a recognized complication of the standard Glenn shunt to the right pulmonary artery. Angiographic study of Glenn shunts should be routinely obtained to detect the presence of venous collaterals,

Figure 52.23. Anteroposterior and lateral views of selective ventricular injections in three morphologic types of DILV. (Top panel) illustrates typical features of DILV. Note the pulmonary band and anatomic evidence of subaortic stenosis at the VSD. (Middle panel) demonstrates an example of double-inlet right ventricle with double-outlet right ventricle and an anterior aorta. A hypoplastic rudimentary LV is noted posteriorly (*arrow*). (Bottom panel) demonstrates double-inlet indeterminate ventricle with pulmonary atresia. The ventricle is coarsely trabeculated and irregular, but no hypoplastic LV could be identified.

pulmonary artery stenoses, and pulmonary arteriovenous fistulae. However, contrast echocardiography demonstrating contrast effect appearing within the right pulmonary veins remains a most sensitive method for detection of fistulae. Demonstration of a lower right pulmonary venous blood oxygen saturation compared with the oxygen saturation of the left pulmonary venous blood also may suggest the presence of right pulmonary arteriovenous fistulae.

Systemic Circulation

Aortic arch anatomy should be adequately demonstrated by ventricular angiography or by selective injections to delineate the location of the aortic arch, to obtain the status of the brachiocephalic branches, and to exclude significant coarctation of the aorta. The progressive ventricular hypertrophy and decreased ventricular compliance secondary to the systemic

Figure 52.24. Anteroposterior view of selective ventricular injection in patient with situs solitus, mesocardia, double-inlet ventricle of mixed myocardial morphology. The aorta is anterior and slightly to the left of the pulmonary artery. Angiographically, the ventricle is divided into a smooth-walled left ventricular (LV) zone on the patient's right and a trabecular right ventricular (RV) zone on the left, consistent with embryologic L-ventricular looping. Both great arteries originate from the right ventricular zone. The patient underwent a modified Fontan procedure.

hypertension and increased afterload associated with significant coarctation of the aorta are hemodynamic conditions that are poorly tolerated following modified Fontan operation. Preoperative assessment should include angiographic or catheter pressure measurements to exclude this associated lesion. Also, patency of surgically placed systemic pulmonary shunts, persistent ductus arteriosus, or systemic pulmonary collateral vessels should be determined preoperatively with aortic or selective arterial angiography.

Treatment

Rarely, unoperated patients with perfectly balanced circulation may survive into the sixth decade (24). Palliative surgical procedures are important to protect the integrity of both the pulmonary vascular bed and the myocardium. Pulmonary artery banding has been recommended for patients with univentricular AV connection without pulmonary stenosis. Uncontrollable congestive heart failure, excessive pulmonary blood flow, and severe pulmonary hypertension should prompt pulmonary artery banding in early infancy (i.e., younger than 6 months of age) to prevent the development of pulmonary vascular obstructive disease. When performed, pulmonary artery banding should be monitored carefully to determine that reduction of the pulmonary blood flow reduces the pulmonary pressure to normal levels. Even mild elevations of pulmonary vascular resistance (3 U/m^2) will preclude successful Fontan operation. However, several reports have recognized that some patients with univentricular AV connections subjected to pulmonary artery banding will develop subaortic stenosis (24). One must be cognizant of the potential for development of subaortic stenosis and its consequences. Patients with subaortic stenosis, but without pulmonary stenosis, may require alternative methods to protect the pulmonary vasculature. One option is

to interrupt the pulmonary outflow tract and place a systemic-to-pulmonary artery shunt large enough to provide adequate pulmonary blood flow. If significant subaortic stenosis already is present, an aortopulmonary window together with a distal pulmonary artery band has been recommended.

Progressive cyanosis and secondary erythrocytosis in patients with naturally occurring pulmonary stenosis may require a systemic-to-pulmonary artery shunt. The modified Blalock–Thomas–Taussig (BTT) shunt uses a Gore-Tex graft from the subclavian artery to the pulmonary artery. It is preferred because it does not require ligation of the subclavian artery and the length of graft is not limited. Beyond the first 4 to 6 months of life, the bidirectional cavopulmonary connection (bidirectional Glenn shunt) is an effective means of providing long-term palliation for patients with univentricular connection. The bidirectional cavopulmonary shunt includes anastomosis of the cardiac end of the superior vena cava to the right pulmonary artery but leaves the pulmonary arteries confluent. The bidirectional Glenn shunt provides effective pulmonary blood flow by directing desaturated blood directly into the pulmonary circuit. It does not increase the ventricular volume load as does a systemic-to-pulmonary shunt.

Previously, the classic Glenn shunt was the preferred technique, consisting of anastomosing the superior vena cava to the right pulmonary artery resulting in nonconfluent pulmonary arteries. Several serious complications and disadvantages however became increasingly recognized and as result, the classic Glenn is no longer done routinely (25). The most significant complication was the development of pulmonary arteriovenous fistulae. They develop around 5 years after placement of the Glenn shunt. Other significant disadvantages include loss of confluence between right and left pulmonary arteries, distortion or stenosis of the superior vena cava or the right pulmonary artery, right pulmonary artery thrombosis, abnormal right pulmonary blood flow distribution, and failure of the right pulmonary artery to develop normally.

Although the bidirectional cavopulmonary shunt produces excellent palliation in the first 2 to 3 years of life, progressive cyanosis and secondary erythrocytosis usually prompt further palliative efforts to improve pulmonary flow. If the pulmonary arteries remain hypoplastic, an additional systemic-to-pulmonary shunt may provide greater pulmonary blood flow for relief of cyanosis and promote growth of the pulmonary vascular bed. In general, the bidirectional cavopulmonary shunt alone does not provide sufficient pulmonary blood flow to palliate adequately patients with univentricular AV connection to childhood.

Three options for more definitive surgical correction of patients with univentricular AV connection are ventricular septation, modified Fontan operation, and cardiac transplantation (19–26). In 1956, Kirklin performed a septation operation in a 12-year-old patient who had a single ventricle with a small ridge of apical ventricular septum. Based on this and similar early successes, the initial efforts at surgical correction of univentricular AV connection were directed toward ventricular septation or placement of a prosthetic patch to separate the MVC into right and left components, basically in a plane between the two AV valves. The earliest report by McGoon et al. (27) described the most successful early septation results in patients with DILV and left-anterior subaortic right ventricle (A-III single ventricle). However, early mortality rates were high, approximately 38% to 40%, and subsequent reports noted similar results (27,28). A progressive late mortality rate secondary to ventricular failure, progressive AV valve regurgitation, residual left-to-right shunts, conduit failure, and complete heart block prompted abandonment of this method of surgical correction for univentricular AV connection.

The modified Fontan procedure with direct atriopulmonary connection and a lateral right atrial tunnel to produce a

bicaval bidirectional or “total” cavopulmonary anastomosis have become common methods for a more definitive surgical “correction” or palliation for patients with univentricular AV connection. Also, the bidirectional caval pulmonary anastomosis and an added external or internal conduit from the inferior vena cava to the right pulmonary artery are optional methods for surgical repair. Although initial surgical reports from 1973 to 1980 suggested that the mortality for modified Fontan procedure was somewhat higher for patients with single ventricle (21%) than for patients with classic tricuspid atresia (17%) (26), current results (1988 to 1992) indicate substantial improvement with the same early mortality rate of about 4% for both tricuspid atresia and DILV (29). Even the more complex forms with common-inlet AV connection and situs ambiguus have early mortality rates of approximately 11% when stronger screening efforts are used to provide better patient selection, as described in the catheterization section. Earlier operation, that is, when the patient is between 2 and 3 years of age, is now recommended to avoid complications related to long-term ventricular volume overload, hypoxia, cyanosis, AV valve regurgitation, pulmonary artery distortion, and pulmonary hypertension. Surgical techniques have improved to provide more efficient and direct flow from the caeae into the pulmonary arteries by lateral tunnels or external conduits and direct anastomoses described as bicaval, bidirectional, or total cavopulmonary connections. Such direct connections seem to provide more efficient and directed flow to the pulmonary artery and avoid dilated atrial chambers that appear to promote blood stasis and pooling with potential for thromboses and atrial arrhythmias. The use of a lateral tunnel, intra-atrial, or extracardiac conduits in univentricular connection also provides greater flexibility for management of patients with common and single-inlet connections and avoids the necessity for AV valve patch closure in double-inlet connections. Some reports suggesting extremely poor results and high mortality rates in earlier series (1973 to 1983) typically included older and more debilitated patients prior to attempted repair and did not reflect recent improvements in medical and surgical management currently available (29).

Current data from the long-term evaluation of postoperative univentricular AV connection patients continue to demonstrate generally satisfactory results in most patients after the modified Fontan procedure (29,30). Most surviving patients report a subjective improvement in their quality of life and exercise tolerance compared with their preoperative conditions. A number of reports reviewed some of the hemodynamic abnormalities, rhythm disturbances, and protein-losing enteropathy that have been recognized in late survivors following modified Fontan procedure. Mechanical causes for a poor clinical result and high right atrial pressure include obstruction of caval or atriopulmonary connections, pulmonary artery distortion or hypoplasia, pulmonary vascular obstructive disease, pulmonary venous obstruction, poor ventricular function, significant AV or semilunar valve regurgitation, and residual left-to-right shunts. Elevated right atrial pressures also result in right atrial distension and stretching of the right atrial wall. Significant arrhythmias have been reported following modified Fontan procedure and are primarily supraventricular in origin. They have included atrial flutter, primary atrial tachycardia, atrial fibrillation, and accelerated junctional tachycardia. Medical management and antitachycardia pacing devices have been used successfully to control these rhythm disturbances.

Orthotopic cardiac transplantation also has been used successfully in chronically debilitated patients who have a variety of congenital cardiac defects, including univentricular AV connection. Usually, patients with severe ventricular dysfunction following modified Fontan procedure have experienced progressive physical deterioration and have required cardiac transplantation for survival. Although the early surgical results for

these patients have been encouraging, the long-term morbidity and mortality rates for cardiac transplantation have not warranted consideration of cardiac transplantation as the first or primary option for surgical management of patients with univentricular AV connection. In spite of the apparent benefits, 40 years of experience with the Fontan procedure have gradually revealed the shortfalls of such a circulatory arrangement. Sequelae related to the underlying congenital anomaly or to the altered physiology of passive, nonpulsatile flow through the pulmonary arterial bed commonly contribute to an increasing incidence of failure of the Fontan circulation over time (31). Morbidities include rhythm disturbances, thromboembolic events, protein-losing enteropathy, systemic ventricular dysfunction, and heart failure (31–33). Extracardiac late complications also appear to be common. These late extracardiac complications include restrictive lung disease, renal dysfunction, and liver dysfunction (34–36). Liver abnormalities include clotting cascade, cirrhosis, and hepatocellular carcinoma (36). The clinical significance of these findings, however, remains poorly understood (36).

We, therefore, currently recommend palliative support, including selected pulmonary artery banding and systemic-to-pulmonary shunts in univentricular AV connection patients during the first 6 months of life. If significant subaortic obstruction is present, an aortopulmonary window and an endoluminal banding operation should be performed early to prevent ventricular hypertrophy and to protect the pulmonary vasculature. After 6 months of age, a bidirectional cavopulmonary shunt could be considered to increase pulmonary blood flow and to reduce ventricular volume loading. This, in conjunction with additional pulmonary flow through the native pulmonary outflow tract or a small systemic-to-pulmonary shunt, should provide adequate pulmonary blood flow to reduce cyanosis and promote growth of the pulmonary arteries without substantial ventricular volume overload. If this provides adequate palliation, a complete modified Fontan procedure could be considered when the patient is between 2 and 3 years of age.

Cardiac Malpositions and Abnormalities of Atrial and Visceral Situs

Patrick W. O'Leary ■ Donald J. Hagler

Cardiac malposition describes an abnormal or anomalous location of the heart. Our discussion of cardiac malposition includes abnormalities of overall cardiac position (dextrocardia, mesocardia, levocardia [isolated]), as well as pericardial defects, and the complex anomaly of ectopia cordis (1,2). Cardiac malpositions often are integral components of complex cardiac anomalies involving abnormal visceral and atrial situs (sidedness). Due to the complex nature of these groups of anomalies, pathologists and clinicians have pursued a logical, systematic, and consistent method of analysis typically described as a segmental approach to the diagnosis of congenital heart disease. This approach begins with a description of the asymmetrically arranged organ systems of the abdomen and thorax (determination of situs), proceeds to define the cardiac position and orientation within the chest, and concludes with a detailed description of the venous, cardiac, and arterial segmental anatomy, as well as the spatial relationships of the segment components and the connections of adjacent segments to one another (see Chapter 2).

DEFINITIONS

Understanding of the often complex malformations associated with abnormal cardiac position is facilitated by a clear definition of the terminology used to describe them.

The classification of overall cardiac position is determined by the cardiac base–apex axis as illustrated in Figure 53.1. **Dextrocardia** has been defined classically and most consistently as the location of the heart in the right hemithorax with the apex pointing (base–apex axis) to the right. Dextrocardia may occur with atrial situs solitus, situs inversus, or situs ambiguus. When it occurs with situs solitus, it also has been called isolated dextrocardia. Although the normal heart can be “shifted” into the right chest by a variety of extracardiac processes (diaphragmatic hernia, tumors, or tension pneumothorax), these situations, in which the cardiac base–apex axis is still oriented to the left, are better described as “dextroposition,” rather than dextrocardia.

Mesocardia is the location of the heart with the cardiac base–apex axis directed inferiorly in the midline of the thorax (neither to the right nor left). The ventricular apices are equally directed to both right and left side of the sternum. This anatomic description of cardiac malposition often is ignored as being infrequent and atypical. However, many cases accepted as having dextrocardia may be described more accurately as mesocardia, because of a midline cardiac position. Most cases of mesocardia have been described with situs solitus. However, mesocardia also has been described with situs inversus and situs ambiguus.

Levocardia as a cardiac malposition only is considered as isolated levocardia, occurring in conjunction with situs inversus and situs ambiguus. Thus, despite an abnormal atrial and

visceral situs, the heart is in its normal location in the left hemithorax with the apex (base–apex axis) pointing to the left.

Situs (or sidedness) is a term used to describe the spatial relation of an asymmetrically arranged organ system (or group of related organs). For our discussion, the situs of the abdominal organs (stomach, liver, bowel, and spleen) and the atria would receive the most attention. **Situs solitus** describes the normal site or position of the viscera or atria. Typically, both must be independently considered and described for a precise segmental approach. **Situs inversus** describes an inversion or right/left reversal of visceral or atrial site or position, i.e., a mirror image of the normal situation. In cases of atrial situs inversus, the right atrium will lie to the left and the anatomic left atrium to the right. Abdominal situs inversus consists of a right-sided stomach and spleen, and a left-sided liver. **Situs ambiguus** describes an uncertain or indeterminate visceral or atrial position because of symmetric or indeterminate anatomy bilaterally. Frequently, patients with abdominal situs ambiguus will have a liver that is “bilateral” and in a midline position, and absence of the spleen (asplenia) is common. Figure 53.2 schematically illustrates the three types of visceral–atrial situs.

Heterotaxia is the term used to describe an anomalous position of the viscera. In humans, anatomic left–right asymmetry is established during embryogenesis. Variations from the normal situs solitus result in heterotaxy, expressed as either randomization (situs ambiguus) or complete reversal of visceral position as in situs inversus. In 1993, Casey et al. (1,2) localized a genetic defect in familial heterotaxy. They found an X-linked recessive trait associated with the inability of the developing embryo to establish normal left–right asymmetry. They later localized this deletion to X q26.2. They further reported that familial heterotaxy occurs with autosomal dominant, recessive, and X-linked inheritance. Kato et al. (3) and Peeters et al. (4) have reported *de novo* balanced translocations involving chromosome band 6q21 in a patient with heterotaxy and left isomerism. Genes implicated in human heterotaxy include *Zic3*, *LeftyA*, *Cryptic*, and *Acvr2B* (5). Both situs ambiguus and situs inversus can appear in some families with heterotaxy.

SEGMENTAL DIAGNOSIS

A segmental approach implies a systematic and therefore sequential review of all structures involved by the congenital anomalies. This sequence would determine the pathologic status of the viscera, the atria, the atrioventricular (AV) connection(s), the ventricles, the ventriculoarterial (VA) connection(s), and the great arteries.

Pathologists have emphasized cardiac segments as the anatomic and developmental components of all human hearts. Van Praagh included ten cardiac segments from an embryologic standpoint: the sinus venosus, the primitive atrium, the common pulmonary vein, the AV canal, the primitive ventricle

Figure 53.1. Cardiac positions. Pathologic specimens of anatomically corrected TGA. **A:** Dextrocardia. **B:** Mesocardia. **C:** Levocardia. The base–apex axis of the heart defines the type of cardiac malposition. Note that with mesocardia there are two relatively well-defined apices of the heart defined by each ventricle but with the major axis of the heart directed in the midline.

(proampulla), the proximal bulbus cordis (meta-ampulla), the infundibulum (conus), the truncus arteriosus, the aortic sac, and the arterial arches (6). However, from a practical clinical approach, some embryologic segments have little relevance or application for anatomic or pathologic examination.

Therefore, a more practical clinical and pathologic segmental analysis begins with definition of major organ positions (visceral situs, atrial situs, and cardiac position/orientation), followed by a detailed description of four segments and the three connections between them. The seven components of this sequential system are (a) the venous segment (systemic and pulmonary veins, plus the coronary sinus), (b) the venoatrial connections, (c) the atria and the atrial septum, (d) the AV connection(s), (e) the ventricles and the ventricular septum, (f) the ventriculoarterial (VA) connection(s), and (g) the great arteries (aorta, pulmonary arteries, coronary arteries, and ductus arteriosus). Table 53.1 illustrates a basic strategy for segmental diagnosis including many criteria and anatomic features that must be determined for accurate diagnosis. This approach should be applied regardless of the method of examination being used (clinical imaging or pathologic examination).

VISCERAL AND ATRIAL SITUS ABNORMALITIES

As illustrated in Table 53.1, the evaluation begins with definition of visceral and atrial situs. Visceral (abdominal) situs is determined by the positions of the liver and stomach (Fig. 53.1). The pancreas and spleen generally are located on the same side of the vertebral column as the stomach. Atrial and visceral situs generally are considered together because they are concordant in most cases (the atrial and visceral situs are the same). However, exceptions occur, and venous connections and visceral situs may not necessarily agree with the apparent atrial situs. These features can be particularly variable in situs ambiguus. Situs ambiguus may be best defined as an uncertain or indeterminate situs (organ positions do not fit into any

standard category). However, in many cases, the right and left components appear very similar to each other, and have been described as mirror images. Such cases also have been referred to as “isomeric” or as having *bilateral* right or left sidedness.

In visceral situs ambiguus with right isomerism (bilateral right sidedness), the spleen is usually absent (asplenia) and the liver is centrally located, symmetrically straddling the midline. In this situation, two mirror-image morphologic right hepatic lobes are present. In contrast to the normal arrangement, the inferior vena cava (IVC) and abdominal aorta will be found on the same side of the vertebral column. In addition, these patients almost always will have malrotations of the bowel.

Situs ambiguus with polysplenia has been described as bilateral left-sidedness or left isomerism (5–12). However, the degree of right/left symmetry is less pronounced in cases of polysplenia than in those with asplenia and bilateral right sidedness. In fact, the most common arrangement of the abdominal viscera in polysplenic patients is more consistent with situs inversus. As a teaching tool, the concept of isomerism (mirror image sidedness) is an attempt to simplify (group) the typical features of complex anomalies in which multiple abnormalities tend to occur together as a syndrome. Thus, the asplenia syndrome (Ivemark syndrome) appears as a pathologic grouping of features emphasizing right sidedness, such as bilateral right bronchi and bilateral right (trilobed) lungs, bilateral right atria, and a symmetrical liver. Ivemark described the implications of asplenia on the pathogenesis of conotruncal anomalies in 1955. Van Mierop et al. (12) pointed out that the asplenia syndrome is associated with pulmonary stenosis or atresia, whereas in polysplenia syndrome, presence of single ventricle physiology and obstruction to pulmonary arterial blood flow are less common. In contrast, interruption of the IVC with azygous continuation of the inferior venous system and anomalous, bilateral pulmonary venous connection of each lung to the ipsilateral atrium are common in polysplenia, but rare in asplenia.

Although splenic anomalies often are associated with complex congenital heart disease and with abnormalities of

Figure 53.2. Cross-sectional drawings of the abdomen illustrating visceral anatomy similar to that observed echocardiographically during a short-axis scan of the abdomen from a costal position. They demonstrate the three basic types of visceral atrial situs: situs solitus (A), situs inversus (B), and situs ambiguus (C,D). The cross-sectional relationships of the visceral structures are easily defined relative to fixed structures such as the vertebral body (Vert) and the diaphragm. The diaphragm limits the abdominal cavity so that posterior structures such as the aorta (Ao) and the azygous continuation of the IVC are retroperitoneal structures, as demonstrated in (D). Separate hepatic venous connections may be present in situs ambiguus, as evident in (C). (ESO, esophagus.)

visceral situs, they are not the cause. Embryologically, the spleen, in contrast to the other thoracoabdominal viscera, does not initially develop as a midline structure. Rather, the splenic anlage is left-sided from its inception. As a result, in the case of bilateral right-sided symmetry, the spleen would not be expected to develop—hence the association of right isomerism with asplenia. In contrast, left isomerism frequently is associated with polysplenia, although multiple spleens are usually found on only one side of the vertebral column (along the dorsal aspect of the stomach).

Clinically, the identification of the morphologic right atrium is important for establishing atrial situs. This is due to the fact that much of the anatomic left atrium is derived from the embryonic common pulmonary vein. As a result, its walls are relatively smooth and lack distinctive features for identification by clinical imaging modalities. In contrast, the anatomic right atrium is derived from the primitive atrium and has several muscular structures that make it more recognizable. Its most reliable anatomic hallmark is the relatively thick superior

limbus of the fossa ovalis, which can be observed by direct inspection at operation, at autopsy, or by tomographic imaging techniques (echocardiographic, CT, or cardiac MR scanning). In cases in which the atrial septum is absent, distorted, or cannot be visualized, atrial morphology may be inferred by inspection of the free atrial wall. A morphologic right atrium contains a large pyramidal appendage, a crista terminalis, and pectinate muscles (13). Angiographically, identification of the morphologically right atrium usually is inferred based upon the presence of large, wide-based, triangular atrial appendage, because the limbus and pectinate architecture cannot be visualized with this type of projection imaging. In situs ambiguus and other complex cases, the atrial septum essentially can be absent, resulting in a common atrium. In these cases, assignment of atrial “identity” can be challenging. The presence of pectinate muscles and the crista is helpful in anatomic specimens. However, when imaging a patient, the connection of the coronary sinus and/or the suprahepatic segment of the IVC can provide a reasonable marker identifying the position of

TABLE 53.1

Segmental Approach to Evaluation of Complex Congenital Heart Disease

Visceral, atrial situs and cardiac position/orientation
The venous segment
Systemic: superior and inferior caval position, number, and connections
Hepatic veins
Coronary sinus
Pulmonary venous connections
The AV connections (morphology/function)
Valve "number," morphology, and commitment (AV malalignment—overriding, crisscross)
Insertion of valvar supports (chordal attachments; septal versus intracavitary, straddling, ...)
Leaflet anomalies (thickening, clefts, fenestrations, ...)
Papillary muscles (position, number, abnormality—parachute)
Valvar function (stenosis, regurgitation)
Functional status (regurgitation, stenosis)
The ventricular segment
Ventricular morphology
- Relative AV valve septal insertion/hinge point (more basal—LV, more apical—RV)
- Papillary muscle anatomy (large, discrete, midcavitary—LV, irregular, small and multiple—RV)
- Endocardial appearance (smooth with small trabeculae—LV, multiple, coarse trabeculae with a moderator band—RV)
Ventricular positions (relative to the other ventricle, to any VSD, and to the great arteries)
Ventricular free walls (hypertrophied, thin, dyskinetic, ...)
Ventricular septum (intact, defect(s), malalignment, ...)
AV valve chordal attachments (relative to the outlets, or any VSD)
Functional assessment (systolic contractility, diastolic relaxation)
The ventricular–arterial connection(s)
Number, patency vs. atresia, and appropriateness (concordant/discordant) of connections
Relative position of the semilunar valves to
- any VSD (override, remote, ...)
- any other outlet valve (normal, side-by-side, right anterior aorta, left anterior aorta)
Functional assessment (stenosis, regurgitation)
The great arteries (aorta, pulmonary arteries, coronary arteries, and the ductus)
Identification of the presence (absence/atresia) and size of each vessel
Identification of relative spatial relationships between vessels
Definition of the extracardiac course and branching patterns
Aortic arch location (right, left) and the brachiocephalic branching pattern
Arch anomalies (hypoplasia, coarctation, patent ductus arteriosus)

AV, atrioventricular; VSD, ventricular septal defect

the morphologic right atrium (14,15). Anatomic determinants of the other cardiac segments also have been described and are summarized in Table 53.2.

One can encounter cases of truly bilateral right atria (or right atrial isomerism). In these patients the appearance of both atrial appendages and the atrial free walls will have the characteristics of a right atrium (Fig. 53.3). Even more rarely, in polysplenia syndrome with left atrial isomerism, both atrial appendages and free walls typically resemble a left atrial appendage. The left atrial appendage usually has a narrow base

and a tubular, hooked shape (13) (Fig. 53.2) (16). However, the atrial appendage shape often is quite variable and may be described best in some instances as simply abnormal. In most cases with asplenia or polysplenia, the atrial anatomy is poorly defined, with a large common atrium, a thin rudimentary remnant of atrial septum, anomalies of systemic and pulmonary venous connections, and abnormal but similarly shaped bilateral appendages. Van Praagh et al. (14) have argued that the concept of bilateral or two right atria and bilateral or two left atria is anatomically unrealistic. These researchers and also

TABLE 53.2 Anatomic Features of Cardiac Segments

Right Atrium	Left Atrium
Thick, superior limbus of fossa ovalis	Thin valve of the fossa ovalis
Large pyramidal appendage	Ostium secundum
Crista terminalis	Small finger-like appendage
Pectinate muscles	No crista terminalis
Receives suprahepatic IVC, coronary sinus	No pectinate muscles
Tricuspid valve	Mitral valve
Septal chordal attachments	No septal chordal attachments
Apical septal annular attachment/hinge	Basal septal annular attachment/hinge
Triangular orifice (midleaflet)	Elliptical orifice (midleaflet)
Three leaflet AV valve	Two leaflet AV valve
Multiple, small papillary muscles	Two large papillary muscles
Empties into RV	Empties into LV
Right ventricle	Left ventricle
Large apical trabeculations	Small apical trabeculations
Coarse septal surface	Smooth upper surface
Moderator, septal and parietal bands	No moderator, septal or parietal band
Receives tricuspid valve	Receives mitral valve
Tricuspid–pulmonary discontinuity - muscular outflow tract (infundibulum)	Usually mitral–aortic continuity
Crescentic in cross section	Circular in cross section
Pulmonary valve	Aortic valve
Empties into pulmonary trunk	Empties into ascending aorta

IVC, inferior vena cava; SVC, superior vena cava.

De la Cruz and Nadal-Ginard (15) emphasized the importance of the suprahepatic segment of the IVC as a reliable marker for the morphologic right atrium, because embryologically, the sinus venosus is incorporated into the right atrium, and IVC-to-right atrium concordance is diagnostically accurate, even when there is viscerotransposition. With incorporation of the sinus venosus, the coronary sinus also can be recognized as a reliable marker for the morphologic right atrium. The morphologic right atrium, then, can be determined by a normally formed coronary sinus, a larger and more anterior appendage, and connection of the suprahepatic portion of the IVC. This approach allows clinical assignment of atrial situs in most cases, although the most important clinical issues are often related to the position and spatial arrangement of the venoatrial connections rather than the morphologic identities of the atria themselves.

Pulmonary situs is determined by the sidedness of the morphologic right and left lungs. Clinically, this is defined by the relationship of the pulmonary arteries to their adjacent bronchi, and not by the number of lobes in each lung. In a morphologic right lung, the pulmonary artery travels anterior to the upper lobe and intermediate bronchi. In contrast, a morphologic left lung is characterized by a pulmonary artery that courses over the main bronchus and posterior to the upper lobe bronchus. The distance from the carina to the origin of the upper lobe bronchus is 1.5 to 2 times greater for the morphologic left lung than for the right lung (17). These relative distances may be used clinically to infer pulmonary situs. The

simplest method is by examination of the air bronchograms on a plain chest x-ray. This ratio applies regardless of the sidedness of the aortic arch (i.e., regardless of the bronchus over which the aorta travels) (Fig. 53.4). In the setting of pulmonary isomerism (both lungs having the same morphology), however, the ratio approaches unity, because the lengths of the two main bronchi are similar. In these cases, bilateral trilobed (right) lungs should suggest the diagnosis of situs ambiguus with the asplenia syndrome (right isomerism), and bilateral bilobed (left) lungs the polysplenia syndrome (left isomerism). However, lung isomerism does not exist in all cases of cardiac isomerism and pulmonary isomerism can occur in patients without features of cardiac heterotaxia.

The cardiac and vascular segments are evaluated not only according to morphology but also in terms of spatial orientation. For example, atria and ventricles should be described both by their morphology and right or left sidedness. In general, the position and orientation of the ventricular septum is used to describe the location of the ventricular chambers. In hearts with levocardia with normally positioned ventricles, the right ventricle (RV) is to the right and anterior, while the left ventricle (LV) is left and posterior. In contrast, in situs inversus totalis the usual ventricular arrangement is the LV—right posterior and the RV—left anterior. Mesocardia is characterized by a vertical midline septum with side-by-side ventricles. Rarely, the ventricular septum is horizontal rather than vertical and results in superior-inferior (over-and-under or “upstairs-downstairs”) ventricles.

Figure 53.3. Atrial appendage anatomy. Pathologic specimen illustrating the anatomic features of the morphologic right and left atrial appendages with left-juxtaposed atrial appendages. The right atrial appendage (RAA) has a large pyramidal shape with a broad base, whereas the left atrial appendage (LAA) has a narrow base and a tubular, hooked, or irregular shape. (LV, left ventricle; RV, right ventricle.) (Provided by Dr. William D. Edwards.)

The position of the aorta is described relative to the pulmonary trunk. Normal hearts are characterized by a right posterior aorta. After the morphology and position of the cardiac segments are determined, the manner in which they connect to one another is evaluated. The three forms of connections to be investigated are venoatrial, AV, and VA.

The difficulties encountered in the accurate definition of atrial situs based on atrial anatomy alone emphasize the importance of accurate determination of systemic and pulmonary venous connections, as described in Tables 53.1 and 53.2. Regardless of the designation of a right or left atrium or the shape of the atrial appendages, the localization of the superior

vena cava (SVC), IVC, hepatic veins, coronary sinus, and pulmonary venous connections should be determined individually and recognized as unilateral or bilateral. This determination is particularly important for surgical management and should be a routine part of any imaging study.

ATRIOVENTRICULAR CONNECTIONS AND ATRIOVENTRICULAR VALVE MORPHOLOGY

The AV connection defines which atrium is connected or aligned with which ventricle. The normal AV connection, or right atrium-to-RV connection, defines a concordant AV connection, whereas a discordant connection is the abnormal connection of the right atrium to the morphologically LV. The term ventricular inversion also has been used to describe a discordant AV connection, but this terminology does not convey the central nature of the connection to these malformations. Discordant AV connections develop during the embryonic process of cardiac looping. The normal looping process begins with the embryonic heart tube bending and growing anteriorly and to the right, allowing the right horn of the sinus venosus to associate with the precursor of the RV. This has been described as a d-ventricular loop and results in AV concordance. In contrast, it is inferred that AV discordance develops due to a defect in cardiac looping, with the heart tube bending anterior and to the left (l-loop). A simplified form of the ventricular loop rule as proposed by De la Cruz et al. (18) and illustrated by Van Praagh et al. (8) is demonstrated in Figure 53.5, which presents four clinical conditions associated with d- or l-ventricular looping. Although originally proposed as an embryologic hypothesis to explain ventricular inversion, there has been mouse embryo documentation that both ventricular d- and l-loops do occur (19). Although this study demonstrated the occurrence of l-loops in mouse embryos with situs inversus, it did not document the occurrence of l-looping as the cause of AV discordance.

The concept of d- and l-ventricular looping has been developed further and defined anatomically in terms of chirality

Figure 53.4. Normal bronchial anatomy. Pathologic specimen (A) and drawing (B) illustrate normal tracheobronchial branching pattern as observed from anterior. The left bronchus and lung are on the right side of each image. Note that the length of the left bronchus from the carina to its first branch is normally 1.5 to 2 times as long as the length of the right bronchus from the carina to its first branch. This anatomic feature allows prediction of the pulmonary visceral situs based on measurements of the bronchial length. (Provided by Dr. William D. Edwards.)

Figure 53.5. Cardiac loop formation as observed embryologically with the loop rule for ventricular localization as proposed by De la Cruz et al. (17) as an explanation for corrected transposition of the great arteries. d-Ventricular looping would result in normal ventricular situs, with the morphologic right ventricle to the right and anterior and the morphologic left ventricle to the left and posterior. l-Ventricular looping would result in inverted ventricular situs. (A, anterior; P, posterior; R, right; L, left; V, ventricle; RV, right vent; LV, left vent; BC, bulb cardis; TA, truncus arteriosus.) (From Van Praagh R. Malpositions of the heart. In: Moss AJ, Adams FH. *Heart Disease in Infants, Children, and Adolescents*. 1st ed. Baltimore, MD: Williams & Wilkins, 1968:604, with permission.)

(20,21) to explain other more-complex abnormalities of ventricular situs (criss-cross relations, as discussed below). The concept of chirality has been used to easily predict the ventricular “loop” that led to a particular malformation based on a right- or left-handed orientation as illustrated in Figure 53.6. The type of AV connection is associated with intrinsic variations of AV conduction tissue pathways.

The concepts of AV concordance or discordance usually will adequately define the type of AV connection in biventricular situations. Other more complex malformations can be described based on their presence (or absence), number, and their relationship(s) to the ventricular inlet(s). These abnormal categories of AV connection, whether concordant or discordant, include absent (atretic), overriding, and crisscross and are more fully described in a separate chapter detailing univentricular AV connection. When both atria connect with only one ventricular chamber, a univentricular AV connection applies. The same discussion reviewed the classification of single-, double-, and common-inlet ventricles.

Crisscross AV connection results due to a rotational abnormality of the ventricles (22). The ventricles often have a superoinferior ventricular relationship that appears to result primarily from an abnormally rightward or leftward rotation of the ventricular mass, and crossed AV connections. The right-sided AV inlet relates to the ventricular chamber that forms the left apex, while the left connection is associated with the right (and usually superior) ventricle. These complex abnormalities frequently are associated with large ventricular septal defects (VSDs), allowing overriding AV connections. These frequently are associated with straddling AV valve chordae and/or malaligned AV connections. Straddling is a feature of the tensor apparatus (chordae tendineae and papillary muscles) of an AV valve and indicates anomalous insertion into the contralateral ventricle, either along its septum or its free wall. The severity

Figure 53.6. The use of chirality to describe what is a d-loop and what is an l-loop. The morphologic right ventricle (RV) of d-looped ventricles is right handed. The RV of l-looped ventricles is left handed. The d-loop RV in situs solitus and the l-loop RV in situs inversus totalis are stereoisomers, or spatial mirror images, just as are the right and left hands. Hence, it is possible to diagnose the type of ventricular loop (d or l) no matter what the spatial relationships of the ventricles may be. Whichever hand fits within the morphologically RV such that the palmar surface is toward the septum and the thumb in the inlet and the fingers in the outlet defines the ventricular loop.

of AV valve straddling has been categorized as type A, B, or C, depending on the position of the abnormal straddling chordae.

The simplest form of chordal straddling, type A, occurs when the abnormal chordae are attached to the upper portion (crest) of the ventricular septum (within 1 cm of the VSD), but on the side opposite from the position of the originating AV valve. In cases of Type B straddling, the anomalous chordal attachment is still found on the contralateral septal surface, but more than 1 cm removed from the edge of the VSD. Valves with type C straddling have abnormal chordal attachments that are supported by papillary muscles within the contralateral ventricular cavity or arising from the opposite ventricular free wall.

VENTRICULAR SITUS AND MORPHOLOGY

Complete assessment of this segment includes an assessment of the cardiac base–apex axis to describe the three basic possibilities of levocardia, dextrocardia, or mesocardia as detailed previously. In addition, an evaluation of this segment should incorporate descriptions of the ventricular locations, relationships, function, and morphology, as well the anatomy of the ventricular septum and any defects in it. These details have been covered elsewhere and need not be repeated here.

GREAT ARTERY RELATIONS

The great arterial connections, the spatial relationships between the arteries and their subsequent distribution/branching patterns, must be determined as described in Table 53.1. Eight basic types of great artery relationship are possible based

Figure 53.7. Four basic combinations of atrioventricular and ventricle–great artery relationships schematically displayed for atrial visceral situs solitus and situs inversus. Although these basic combinations do not include all possible variations in ventricular and great artery spatial relationships, the important aspects of atrioventricular and ventricle–great artery connections are demonstrated, allowing an understanding of the possible hemodynamic variables and the surgical manipulation required for correction. (Comp TGA, complete transposition of the great arteries; Con, concordant; Corr TGA, congenitally corrected transposition of the great arteries; Dis, discordant; Isol vent inv, isolated ventricular inversion; Inv, inverted; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.)

on the aortic and pulmonary valve positions at the level of the semilunar valves. They can be best described by the aortic location as follows:

1. Right posterior aorta (normally related)
2. Right lateral aorta (side by side)
3. Right anterior aorta (d-malposed)
4. Directly anterior aorta
5. Left anterior aorta (l-malposed)
6. Left lateral aorta (left side by side)
7. Left posterior aorta (inverted normal)
8. Directly posterior aorta

This type of segmental approach to complex cardiovascular malformations allows prediction of all possible cardiac conditions that could be encountered. Its flexibility depends upon the sequential addition of each cardiac segment and its relevant connections, accounting for all possible combinations of atrial, ventricular, and great arterial anomalies. Figure 53.7 schematically illustrates four typical clinical examples of segmental variations occurring in both atrial situs solitus and situs inversus. The remainder of this chapter is devoted to descriptions of these complex malformations and the other defects associated with them as they are encountered clinically.

DEXTROCARDIA

Dextrocardia with Atrial Situs Solitus

Isolated Dextrocardia with Atrioventricular Concordance and Normally Related Great Arteries

Isolated dextrocardia with AV concordance and normally related great arteries represents a true form of dextrocardia with the cardiac base–apex axis oriented inferiorly and to the right. It has been described using several names, including

pivotal dextrocardia and dextroversion. All the above descriptions try to convey the concept that the heart in this condition appears externally normal, but the apex is rotated toward the right hemithorax. Figure 53.8 illustrates pathologic features of this form of dextrocardia. The heart appears to have twisted to the right. The base–apex axis of the heart is actually directed to the right, and the ventricular and great artery relationships are normal. There were no gross intracardiac defects. In a series reported by Van Praagh et al. (8), 17 of 23 patients had multiple congenital extracardiac anomalies and 17 of 24 cases had congenital heart defects, including VSD, left SVC to the coronary sinus, coarctation of the aorta, secundum atrial septal defect (ASD), anomalous pulmonary venous connections, and complete AV septal defect.

The clinical presentation of patients with this form of dextrocardia depends upon any other lesions that may be present, such as VSD, coarctation, and AV septal defect, rather than upon the malposition itself. The geometric distortion of isolated dextrocardia compounds the clinical differential diagnosis and surgical management. Radiographic findings include the finding of dextrocardia with the heart positioned in the right chest. Volume overload lesions have radiographic evidence of pulmonary hyperperfusion. Bronchial branching patterns are normal. Visceral situs solitus is recognized by the left-sided stomach bubble and right-sided liver. Electrocardiographic findings can be typical for isolated dextrocardia. Atrial activation is normal, and the P-wave frontal plane axis is 70 to 80 degrees. Due to the shift of the ventricular mass toward the right, the frontal plane QRS axis shows a rightward shift or right-axis deviation. The most striking feature is a translocation or shift of the typical horizontal loop R-wave progression into the right chest. Therefore, as typical left precordial leads are observed, a gradual and progressive reduction in the QRS R-wave voltage is observed. It is therefore necessary to obtain additional complete right precordial leads (V3R to V6R) to correctly record the more typical QRS pattern and R-wave progression that is normally expected from the left chest. Other voltage abnormalities would depend on associated congenital cardiac anomalies.

Isolated Dextrocardia with Atrial Situs Solitus, Atrioventricular and Ventriculoarterial Discordance, and Left Anterior Aorta (Corrected Transposition of the Great Arteries with Isolated Dextrocardia)

Isolated dextrocardia with atrial situs solitus, AV and VA discordance, and left anterior aorta is a spatially complex form of congenitally corrected transposition of the great arteries (TGA). Congenitally corrected TGA is the most common complex cardiac malformation associated with dextrocardia and normal atrial situs. Although these hearts meet all the criteria for dextrocardia, the cardiac position is often close to the midline with only a slight rightward dominance, mimicking mesocardia (Figs. 53.9 and 53.10). There is a high incidence of additional cardiac anomalies observed with this form of isolated dextrocardia, including VSD and pulmonary stenosis. A similar group of anomalies associated with double-outlet RV (instead of TGA) has been well documented. Isolated dextrocardia with atrial situs solitus is also frequently seen in double-inlet LV with hypoplastic subaortic RV. Pulmonary atresia, complete AV septal defect, mitral atresia (right AV valve), tricuspid regurgitation (left AV valve) with Ebstein anomaly–like malformation, and anomalous systemic and pulmonary venous connections (especially with a persistent left SVC to the right atrium or directly to the left atrium with an unroofed coronary sinus) have also been reported (6,8,9).

Radiographic and electrocardiographic findings in this form of isolated dextrocardia are similar to those observed in dextrocardia with normally related great arteries.

Figure 53.8. Upper left: Situs solitus, dextrocardia with normally related great arteries. The schematic drawing at (upper right) depicts normal atrioventricular and ventricle–great artery relationships. The pathologic specimen illustrates normal internal morphologic characteristics of both ventricles. (Ao, aorta; APM, anterolateral papillary muscle; CS, crista supraventricularis; LA, left atrium; LV, left ventricle; MV, mitral valve; PA, pulmonary artery; PB, parietal bond; PPM, posteromedial papillary muscle; RA, right atrium; RV, right ventricle; SB, septal band; TV, tricuspid valve; VS, ventricular septum.) (From Van Praagh R, Van Praagh S, Vlad P, et al. Anatomic types of congenital dextrocardia: diagnostic and embryologic implications. *Am J Cardiol* 1964;13:510–531, with permission.)

The ECG shows normal P-wave axis and right QRS axis deviation. However, the initial qR wave of the QRS complex is abnormally directed to the left, consistent with abnormal septal depolarization associated with AV discordance.

Dextrocardia with Situs Inversus

Dextrocardia with Situs Inversus, AV and VA Concordance, and Inverted Great Arteries (Left Posterior Aorta)

Although the atria, ventricles, and great arteries are all inverted from their normal location and spatial relationships, in this form of dextrocardia, there is persistence of

normal AV and VA connections. This form of dextrocardia was not reported with high frequency in pathologic series, perhaps because of normal physiology often associated with it. However, in life it may be one of the more common forms of dextrocardia. In the review of Van Praagh et al. (21), it occurred in only 7 of 24 cases with situs inversus, and all but 2 cases had associated cardiac anomalies. Ventricular septal defect, tetralogy of Fallot, pulmonary atresia, complete AV septal defect, and secundum ASD were observed in this group. The radiographic findings are consistent with visceral situs inversus and dextrocardia. The electrocardiographic findings in this form of dextrocardia include atrial and ventricular voltage changes that are inverted from normal.

Figure 53.9. Isolated dextrocardia. **A:** Posteroanterior chest radiograph demonstrating cardiac malposition consistent with dextrocardia, with the base–apex axis oriented to the right; however, the heart is just slightly to the right of a midline location, illustrating an intermediate position between mesocardia and dextrocardia. **B,C:** Angiocardiograms demonstrating dextrocardia with atrioventricular and ventriculoarterial discordance. They also show a large ventricular septal defect and some degree of pulmonary arterial overriding. (Ao, aorta; LV, left ventricle; PA, pulmonary artery.)

The P-wave axis is directed to the right and inferiorly because of atrial inversion. Other voltage abnormalities depend on the associated cardiac lesions.

Dextrocardia with Situs Inversus, Atrioventricular Concordance, and Ventriculoatrial Discordance with Left Anterior Aorta

Dextrocardia with situs inversus, AV concordance, and VA discordance with left anterior aorta represents an “inverted” form of complete TGA (Fig. 53.11) and is one of the most common reported forms of dextrocardia with situs inversus, occurring in seven of 24 patients in the Van Praagh et al. (21) series. The hemodynamics and physiology are identical to complete TGA with levocardia. The electrocardiogram shows an inverted P-wave axis because of the atrial inversion; however, there may be more evidence of associated right and left ventricular hypertrophy because of transposition physiology.

Dextrocardia with Situs Inversus and Atrioventricular and Ventriculoatrial Discordance, with Right Anterior Aorta

Dextrocardia with situs inversus and AV and VA discordance, with right anterior aorta, is an inverted form of congenitally corrected TGA. It is rare, occurring in only 3 of 136 cases of

dextrocardia (21) (Fig. 53.12). Although the segmental cardiac connections would, theoretically, be physiologically correct in these hearts, there was a high frequency of significant additional associated anomalies, resulting in profound hemodynamic impairments. In the example demonstrated, there is a VSD and subpulmonary stenosis. Also, there is significant cardiac rotation to the right, so that the aorta is actually in a right posterior position relative to the pulmonary valve and main pulmonary artery.

Dextrocardia with Situs Inversus, Atrioventricular Discordance, and Ventriculoatrial Concordance with Inverted Normally Related Great Arteries (Left Posterior Aorta)

Dextrocardia with situs inversus, AV discordance, and VA concordance with inverted normally related great arteries (left posterior aorta) has been described as being similar to isolated ventricular inversion, and shares hemodynamics comparable to those of complete TGA. This is also an extremely rare form of dextrocardia, with only two cases reported in the Van Praagh et al. (21) review. One of these patients had multiple additional cardiac abnormalities, including common atrium, common AV valve, and severe right ventricular hypoplasia.

Figure 53.10. Isolated dextrocardia. Pathologic specimen illustrating the most common form of dextrocardia associated with atrial and visceral situs solitus. There is atrioventricular (AV) and ventriculoarterial discordance. Note the great artery orientation with the left anterior aorta (Ao). The resulting hemodynamics are consistent with the physiology of congenitally corrected transposition of the great arteries. **A:** External view of the heart. **B:** A four-chamber cut demonstrating the pathologic features of AV discordance. The left atrium (LA) connects to the morphologic right ventricle (RV) on the left. The *arrow* points out one identifying feature of the morphologic RV, the typical tricuspid valve attachment to the ventricular septum at a point inferior to the mitral valve attachment. (LV, morphologic left ventricle; RA, right atrium; RAA, right atrial appendage.) (Provided by Dr. William D. Edwards.)

Figure 53.11. Pathologic specimen demonstrating situs inversus, dextrocardia with AV concordance, VA discordance, and left anterior aorta in a 26-week-gestation stillborn fetus. It represents an inverted form of complete transposition of the great arteries. A prominent morphologic right (systemic venous) atrial appendage (RA) and the ascending aorta (Ao) are noted on the left of the fetus. The *arrow* points to the stomach on the right side of the fetus. (PA, main pulmonary artery; RV, right ventricle.) (Provided by Dr. William D. Edwards.)

The eight forms of dextrocardia described above are identical to the eight possible theoretical variations of possible AV and VA connections previously outlined in Figure 53.7.

SITUS AMBIGUUS

Situs ambiguus could be present in association with right atrial (asplenia) or left atrial (polysplenia) isomerism. Dextrocardia with situs ambiguus was the most common form of dextrocardia in the Van Praagh et al. (21) review, occurring in 46 of 136 cases; 27 patients had asplenia and 18 had polysplenia. In the pathologic series reported by Lev et al. (9), 12 of 41 cases were “undetermined” or “presumptive” forms of dextrocardia with some features typical of situs ambiguus. Eight of these patients had asplenia.

ASPLENIA

Three of the six examples of dextrocardia with situs ambiguus and asplenia originally reviewed by Van Praagh and Vlad (6) demonstrated features of common atrium, common AV valve, common-inlet ventricle of right ventricular type, hypoplastic LV, and VA discordance or double-outlet RV with pulmonary atresia or severe stenosis. All had normally related ventricles with the RV to the right (d-ventricular loop) and a right anterior aorta. The remaining three were similar with the exception of the ventricular arrangement. They had the RV positioned to the left of the LV remnant (l-ventricular loop, ventricular inversion)

Figure 53.12. Dextrocardia with situs inversus and atrioventricular and ventriculoarterial discordance (congenitally corrected transposition). **A:** The posteroanterior chest radiograph demonstrates dextrocardia with a right-sided stomach bubble consistent with situs inversus and dextrocardia. The angiocardiograms (**B–E**) demonstrate a catheter in a left-sided inferior vena cava (IVC) joining a left-sided systemic venous atrium (RA), which connects with a morphologic left ventricle (LV) and a left-sided pulmonary artery (PA). Note that the ascending aorta (Ao) is right posterior in relation to the pulmonary valve because of marked cardiac rotation to the right. (VSD, ventricular septal defect.) (From Van Praagh R, Van Praagh S, Vlad P, et al. Diagnosis of anatomic types of dextrocardia. *Am J Cardiol* 1965;15:234–243, with permission.)

and left anterior aorta (Fig. 53.13). As is typical with asplenia, all had multiple anomalies of systemic and pulmonary venous connections. Bilateral superior venae cavae with direct connections to the atria, bilateral pulmonary venous connections (direct right and left pulmonary venous connections to the ipsilateral atrium), anomalous supracardiac pulmonary venous connections, absent coronary sinus, bilateral hepatic venous connections to the ipsilateral atrium, and azygous or hemiazygous continuation of the IVC to the SVC are all typical venous anomalies in situs ambiguus. This constellation of anatomic features is characteristic of situs ambiguus and right isomerism, regardless of the cardiac position (levocardia, mesocardia, or dextrocardia). Eleven patients with dextrocardia and asplenia were observed in the series reported by Stanger et al. (11). All had AV septal defects, and seven of these had ventricular inversion (l-loop) and VA discordance with an anterior left aorta. Two had noninverted ventricles (d-loop) and VA discordance with anterior right aorta, and two had single LVs with an anterior left aorta. Although these were the most common types of anomalies reported, several other variations have been reported. Most patients have some AV valve abnormality, such as common AV inlet, but right or left AV valve atresia is also recognized. Many have an unbalanced form of VSD, most often with left ventricular hypoplasia, but they may have tricuspid valve atresia and right ventricular hypoplasia. Some may have a single ventricle of uncertain or indeterminate morphology with a common AV inlet. As previously noted, most patients with asplenia have pulmonary stenosis or atresia. Aortic atresia is a rare finding in asplenia.

POLYSPLENIA

The features classically included with the polysplenia syndrome and dextrocardia are similar to those just described with asplenia, including common-inlet ventricle of right ventricular morphology and double-outlet RV. However, some outstanding differences are noteworthy, including a lower incidence of associated pulmonary stenosis and a more frequent occurrence of bilateral pulmonary venous connections to the ipsilateral atrium. In addition, patients with polysplenia have had

a much wider variation in the cardiac anomalies described, in many cases having features more typically observed with situs inversus totalis. In the review by Van Praagh et al. (21), the most common form of congenital heart disease associated with the polysplenia syndrome was dextrocardia, atrial situs ambiguus, ventricular inversion, and VA concordance with left posterior aorta. The next most frequent complex observed was dextrocardia, situs ambiguus, ventricular inversion, and VA discordance with left anterior aorta. In the Stanger et al. (11) series, nine patients had dextrocardia and four had AV discordance with VA concordance (ventricular inversion) or double-outlet RV. This review also suggested that situs inversus and polysplenia with dextrocardia may be interrelated etiologically and embryologically. They noted that the associated cardiovascular malformations found in the polysplenia syndrome were similar to, but often less severe than, those found in the asplenia syndrome. For example, only complete common AV septal defects were found in the asplenia syndrome, but partial AV septal defects also were observed in the polysplenia syndrome. Pulmonary outflow tract obstruction (stenosis or atresia) occurred in 5 of 18 patients with polysplenia, whereas pulmonary outflow tract obstruction was present with asplenia in 16 of 18. Features characteristic of the polysplenia syndrome, such as interruption of the IVC with azygous continuation to the SVC and ipsilateral pulmonary veins, also were noted.

LEVOCARDIA (ISOLATED LEVOCARDIA)

When the heart is in a normal position and has a normal base-apex cardiac axis, isolated levocardia implies that either atrial situs inversus or atrial situs ambiguus is present. In the autopsy series reported by Van Praagh et al. (8) and by Stanger et al. (11), atrial situs inversus with levocardia was unusual and occurred in only 3% to 14% of the cases described with isolated levocardia. Most of these had AV discordance and either VA discordance or double-outlet RV with anterior right aorta, resembling malpositioned forms of corrected TGA.

Figure 53.13. Pathologic specimen demonstrating anatomic features observed with situs ambiguus, dextrocardia with asplenia. **A:** Frontal view demonstrating the heart and lungs. The cardiac base-apex axis (arrow) points to the right, consistent with dextrocardia. The lungs are trilobed bilaterally. The aorta (Ao) is left anterior with a right aortic arch. **B:** An open view of the morphologic right ventricle (RV). There was a common-inlet (CAV) RV with double-outlet RV and severe pulmonary stenosis. A white probe is inserted into the stenotic pulmonary outflow tract. The white arrowhead indicates a hypoplastic rudimentary morphologic left ventricle to the right and posterior. The ventricular relationships are consistent with ventricular inversion or l-ventricular looping. (Provided by Dr. William D. Edwards.)

MESOCARDIA

As defined previously, mesocardia is present when the heart is in a midline position and the cardiac base–apex axis is oriented directly inferiorly (neither to the right nor left). Autopsy series (6,8,9,23) have consistently included a very low incidence of mesocardia. The series by Stanger et al. (11) included only patients with asplenia (situs ambiguous). However, the series by Lev et al. (23) included 17 cases with situs solitus, inversus, and ambiguous. Most of these had situs solitus and were either normal hearts or examples of VA discordance with and without AV discordance (complete or congenitally corrected TGA). Lev et al. (23) defined mesocardia as that condition in which the longitudinal axis of the heart lies in the midsagittal plane with the heart possessing no distinct apex. The low incidence of mesocardia in these reports may reflect a tendency to have included such cases in the groups with dextrocardia or isolated levocardia. As a group, the hemodynamic and clinical findings in mesocardia are also similar to those previously described with dextrocardia. Figure 53.1 (panel B) illustrates pathologic findings in a patient with situs solitus and mesocardia, as well as AV and VA discordance.

ECHOCARDIOGRAPHIC FEATURES OF CARDIAC MALPOSITION

Two-dimensional and Doppler echocardiography have become the cornerstone of the initial diagnostic evaluation of patients with all forms of congenital heart disease and provide essential

anatomic data in patients with cardiac malpositions. Transthoracic echocardiography is a convenient and noninvasive technique that can provide most of the clinically relevant information concerning the cardiovascular anatomy and physiology, especially in young patients. In situations where a transthoracic examination is inadequate (i.e., patients with poor transthoracic images, large body size, or postoperative bandaging, etc.) or impossible (during an operation), transesophageal echocardiography can be used to obtain additional echocardiographic information.

Segmental Approach

The echocardiographic approach to patients with cardiac malpositions should follow the sequential segmental analysis that was outlined earlier in this chapter and in many other reports (24–26). The following section and its echocardiographic images of normal and malpositioned hearts are included to illustrate the tomographic anatomy associated with these malformations and to assist the reader in correlating the echocardiographic findings with the previously presented anatomic and angiographic examples of these complex hearts.

Visceral Situs

Images of the liver, hepatic veins, IVC, stomach, spleen, and abdominal aorta are obtained from the subcostal transducer position. The normal position of these organs and vessels is demonstrated in Figure 53.14. Visceral situs inversus is characterized by a left-sided liver and IVC in association with a right-sided stomach, spleen, and abdominal aorta (Fig. 53.15).

Figure 53.14. Atrial and visceral situs solitus. **A:** The subcostal short-axis scan of the abdomen demonstrates an initial right-to-left orientation for visceral situs determination. The spine is readily recognized as a posterior midline structure. The liver mass is noted predominately in the right side of the abdomen. The intrahepatic portion of the inferior vena cava (IVC) is observed on the right and the abdominal aorta (Ao) on the left. The stomach is noted on the left as a bright echo. **B:** A long-axis view of the IVC illustrates the connection of the IVC to the right atrium (RA) consistent with situs solitus. The hepatic vein (HV) is also noted draining to the IVC–RA junction. **C:** With the transducer oriented to the left of the abdomen, the stomach and spleen are identified.

Figure 53.15. Atrial and visceral situs inversus. Subcostal short-axis scan of the abdomen provides right-to-left spatial orientation. The liver (L), inferior vena cava (IVC), and hepatic veins (HVs) are on the patient's left, and the stomach (S) is seen on the patient's right. The descending abdominal aorta (Ao) is directly anterior to the vertebral body (VB).

As previously described, situs ambiguus has been used to describe a wide spectrum of anomalies, including the visceral abnormalities present in the asplenia and polysplenia syndromes (Fig. 53.16). The visceral situs is considered

“ambiguous,” because it does not conform to the classical patterns of situs solitus or inversus. Nearly all possible combinations of abdominal organ and great vessel location have been reported (17,21). The term visceral situs ambiguus does not mean that the positions of the abdominal organs cannot be determined. Their positions and venous connections can and must be accurately defined before corrective surgical procedures can be performed.

The obvious echocardiographic finding in patients with asplenia is the *absence* of or the inability to demonstrate the presence of a spleen. The spleen, when present, is always located posterolateral to the stomach (7,11,17,27). Routine transthoracic echocardiography can easily determine splenic status by locating the stomach and interrogating the area posterior and lateral to the stomach (Fig. 53.14). The splenic tissue may have a denser echocardiographic appearance than the liver and its comma-shaped curvilinear splenic vein may be identifiable. In patients with asplenia, no splenic tissue can be identified in this position; however, both flank areas must be carefully examined. When this echocardiographic finding is associated with the presence of Howell–Jolly bodies on the peripheral blood smear, the diagnosis of asplenia can be made with 100% confidence. Patients with asplenia usually will have a midline liver (a large central liver mass equally committed to both the right and left upper quadrants of the abdomen) (Fig. 53.16). The liver will frequently have two lobes that are relatively equal in size and resemble morphologic right lobes. Occasionally, some of the hepatic veins will connect directly to the atrium instead of draining to the IVC. The positions of the stomach, IVC, and

Figure 53.16. Visceral situs ambiguus: A: Asplenia: subcostal short-axis horizontal-plane image of the upper abdomen in a patient with situs ambiguus and asplenia. Note the large midline liver mass occupying both (especially the left) quadrants of the abdomen. The stomach was on the right side of the abdomen. The inferior vena cava (IVC) and aorta (Ao) both occupy a position directly anterior to the spine with the Ao posterior to the IVC. B: Polysplenia: subcostal short-axis horizontal-plane image of the abdomen in a patient with situs ambiguus and polysplenia. The liver is large and midline. The aorta (Ao) and an azygous (Az) continuation of the IVC are noted on the left side of the spine (VB). The azygous continuation is located posteriorly in the retroperitoneal space. C: Long-axis image in the same patient demonstrating the aorta and the azygous vein. Note that a hepatic vein (HV) enters directly into the common atrium (CA).

Figure 53.17. Polysplenia. Long-axis image from the left flank demonstrating two equal-sized spleens adjacent to the liver and superior to the left kidney. This finding is consistent with the diagnosis of situs ambiguous, with left isomerism.

aorta are more variable than that of the liver, and they must be individually described. Characteristically, the IVC and aorta are both located on the right side of the vertebral column in a parallel anteroposterior orientation (Figs. 53.2 and 53.16).

Patients with polysplenia will have multiple, separate spleens positioned posterior to the stomach (Fig. 53.17). As with asplenia, multiple or multilobulated spleens can be readily detected by echocardiography (27). Other visceral features of the polysplenia syndrome may include interruption of the IVC with azygous continuation and a midline location of abdominal aorta. With interruption of the suprahepatic portion of the IVC, the hepatic veins will connect directly to the atrium. Occasionally, there may be two or more separate hepatic vein connections to the right or left sides of the atrium. The location of the liver and stomach are variable, but most commonly in polysplenia syndrome with cardiac malposition, they are inverted, with the stomach and multiple spleens located on the right side of the abdomen.

Venous Connections

Venous abnormalities are common when cardiac malpositions are present. These abnormalities include, but are not limited to, bilateral superior vena cavae connecting directly to the ipsilateral atrium (absent coronary sinus), interruption of the IVC with azygous or hemiazygous continuation to the ipsilateral SVC, and various anomalous pulmonary venous connections as described earlier in this chapter. Direct pulmonary venous connections to the ipsilateral atrium, as well as complete or partial connections to the right or left SVC can be defined echocardiographically (26,28), especially during the newborn and neonatal period. If transthoracic images are inconclusive, a complete transesophageal study can be helpful to define these abnormal pulmonary venous connections.

Atrial Situs

Once visceral situs and the venous structures and connections have been defined, atrial situs should be determined. These two portions of the exam, however, are intimately related.

Each major venous connection (SVC, IVC, hepatic veins, and each pulmonary vein) to the heart must be identified. Specific attention should be paid to the coronary sinus, when present, as its connection represents a marker for the morphologic right atrium. Additionally, dilation of the coronary sinus may signal an anomalous venous connection, and, unroofing of the coronary sinus should be ruled out, which if undetected could lead to residual atrial shunting after repair.

Although venous connections can assist in determining atrial situs, it is the relationship between septum primum and septum secundum that is the most reliable determinant of atrial situs (7). The thick remnant of septum secundum is best seen by echocardiography as the superior limbus of the fossa ovalis (Fig. 53.18). This limbus will be associated with the morphologic *right atrium*. The thin remnant of septum primum, best seen by echocardiography as the valve of the fossa ovalis, will be associated with the morphologic *left atrium*. Unfortunately, these structures are not always present in patients with congenital heart disease. When the remnants of these septa are absent, other markers for atrial situs must be used. Van Praagh et al. (21) suggest that the connection of the suprahepatic IVC be used as the next most reliable marker. In their experience, the suprahepatic IVC always connects to the morphologic right atrium. The morphology of the atrial appendages also has been used to determine atrial situs (13). Classically, the appendage associated with a morphologic right atrium (Fig. 53.19) is described as a broad, somewhat triangular structure, whereas the left atrial appendage is more of a finger-like, narrow projection. Figure 53.20 demonstrates the echocardiographic features of left-juxtaposed atrial appendages in a patient with double-outlet RV. In this short-axis view, both atrial appendages are well visualized and demonstrate the typical anatomic features described above for the atrial appendages. The connections of the SVC and pulmonary veins are not reliable predictors of atrial situs.

Atrioventricular Connection

The routine evaluation of the AV connection has been described earlier in this chapter. In the presence of cardiac malposition, the echocardiographic evaluation includes an extensive assessment of the AV connection using the segmental approach. Few generalizations are valid with respect to the complex AV connections found in malpositioned hearts, and each type of connection is best considered as unique to the patient being examined. Right and left parasternal short-axis, as well as apical and subcostal four-chamber views, generally, are best used for assessment of the AV connections. As described in Table 53.1, abnormalities of both AV commitment and valve abnormalities must be defined. Echocardiographic examples of three types of abnormal AV connection often observed in cardiac malposition (single-, double-, and common-inlet connections) were discussed in the previous chapter dealing with univentricular AV connections. Figure 53.21 demonstrates an example of dextrocardia with severe overriding and straddling (type C) of the tricuspid valve with AV concordance, illustrating one of the variations on the basic themes that may exist in these complex patients.

Cardiac Base–Apex Axis

Previously, we have defined cardiac malpositions including dextrocardia, mesocardia, and levocardia based on the orientation of the cardiac apex or the cardiac base–apex axis. Not only can the position of the heart in the chest be defined, but also its base–apex axis can be accurately defined echocardiographically. The subcostal transducer position is most useful for making these assessments. The center of the scan plane is positioned at the upper abdominal midline, and coronal images of the heart are obtained. Thus, the position of the

Figure 53.18. Atrial situs. **A:** Subcostal parasagittal view demonstrating the right and left atria in a newborn. The right atrial aspect, the limbus of the fossa ovalis (septum secundum) is identifiable (*arrowhead*), and on the left atrial side, the valve of the fossa ovalis (septum primum) is evident (*arrows*). **B:** Long-axis transesophageal scan of the atrial septum (AS) demonstrating similar anatomic landmarks to define atrial situs. Again the *arrowhead* points to the limbus of the fossa ovalis of the morphologic right atrium (RA). The *arrows* point to septum primum on the left. Note that the right atrial appendage (RAA) is observed anterior and adjacent to the superior vena cava (SVC). The RAA has a broad base and pyramidal shape. (A, anterior; LA, left atrium; P, posterior; RPA, right pulmonary artery; S, superior.)

heart within the thorax can be defined easily. When most of the heart is located to the left of the midline, the heart is then said to have levoposition. When most of the cardiac mass is to the right or evenly spread across the midline, there is dextroposition or mesoposition, respectively. The second component of cardiac position is more anatomically descriptive and involves the cardiac base–apex axis. When the cardiac axis is oriented to the left, levocardia is present (Fig. 53.1). When this axis is oriented to the right or directly inferior, there is dextrocardia or mesocardia, respectively (Fig. 53.1).

As previously described, isolated levocardia and isolated dextrocardia can be associated with various complex congenital anomalies. These diagnoses imply the presence of discordance between atrial situs, and the plane of the atrial septum will be distorted and it will not be found in a plane parallel to the cardiac base–apex axis and ventricular septum. Rather, the bulk of the atrial septum in hearts with isolated dextro- or levocardia will be perpendicular to that plane (Fig. 53.22). As a result of the discordance between the atrial situs and the base–apex orientation, the atrial septum assumes a curved shape that is characteristic of this abnormality.

Ventricles, Ventriculoarterial Connection, and Great Arteries

Ventricular anatomy, ventricular–great artery connection, and the great arteries themselves can be described according to the standard techniques described in earlier echocardiographic reports (25,26). Abnormalities of VA connections and great artery relationships are common in cardiac malpositions. Positioning of echocardiographic scans must be modified from the standard right or left parasternal and subcostal positions to adequately delineate VA connections and great artery relationships in these complex hearts. Parasternal long and short-axis scans are particularly helpful in determining concordant, discordant, or double-outlet connections as described in previous chapters devoted to these specific entities. Figure 53.20B illustrates a parasternal long-axis scan in a patient with

double-outlet RV. The pulmonary artery is demonstrated coursing posteriorly and is primarily committed to the anterior RV. The accompanying short-axis scan illustrates the great artery relationship with left anterior aorta. Additionally, suprasternal scans should be obtained to assess the proximal pulmonary and aortic arch anatomy. The aortic arch should be determined as right or left sided and the brachiocephalic branching pattern defined.

TREATMENT

Treatment of the wide variety of congenital cardiac malformations observed in cardiac malpositions, obviously, must depend on the specific lesion. Surgical correction should be achieved as frequently as possible using a standard two-ventricular-type repair such as an arterial switch procedure (Jatene, Kaye-Damus-Stansel, or Aubert procedure), or with VSD closure connecting the systemic ventricle to the aorta, transection of the pulmonary artery, and establishment of pulmonary ventricle-to-pulmonary artery continuity with an extracardiac conduit.

More complex malformations associated with situs ambiguus, such as common atrium with common-inlet single ventricle or unbalanced ventricles, and complex malformations associated with crisscross AV relations and severe AV valve straddling have fewer options for successful biventricular surgical correction. Most can only be directed toward a single ventricle pathway with systemic–pulmonary artery shunts, Glenn-type shunts, bidirectional cavopulmonary shunts, and finally the modified Fontan procedure.

All such procedures have had moderately increased mortality risks when applied to patients with the more-complex lesions observed in situs ambiguus. When anomalies of systemic and pulmonary venous connection are present, special efforts must also be directed toward surgical establishment of appropriate venous connections or relief of venous stenoses

Figure 53.19. Atrial situs. Composite images showing pathologic and echocardiographic correlates of atrial morphologic features. **A:** Typical anatomic features of right and left atrial appendages (RAA and LAA). **B:** A right parasternal image illustrating the right atrial appendage (RAA), which is broad based and pyramidal. **C:** A specimen showing the inferior vena cava (IVC) draining to the right atrium (RA). **D:** Similarly, a subcostal echocardiogram illustrating the IVC connection to the right atrium and the small finger-like left atrial appendage (LAA) of the left atrium (LA). Ao, aorta.

that may be present. Unfortunately, because of their complex anatomic and situs abnormalities, such patients present significant challenges for cardiac transplantation when this is considered the only possible or one of the best options for surgical management. Medical management of these complex malformations offers little hope for long-term survival because of known complications of progressive hypoxia and polycythemia, progressive ventricular fibrosis, and ventricular failure, stroke, and brain abscess associated with such lesions (5,11,21).

Waldman et al. (29) showed a greatly increased frequency of fulminating and fatal septicemia produced by encapsulated bacteria in patients with the asplenia syndrome compared with appropriate controls. It generally is recommended that some form of antibiotic prophylaxis be given for congenitally asplenic patients. *Klebsiella* and *Escherichia coli* are the principle pathogens in patients younger than 6 months of age, whereas *Streptococcus pneumoniae* (pneumococcus) and *Haemophilus influenzae* predominate after 6 months. The report of the Committee on Infectious Diseases of the American Academy of Pediatrics recommends using continuous antibiotic prophylaxis in infants, children, and adults with the asplenia syndrome. For antimicrobial prophylaxis, oral penicillin V (125 mg, twice a day, for children younger than 5 years of age and 250 mg, twice a day, for children 5 years of age and older) is recommended. Some experts

recommend amoxicillin (20 mg/kg/day) (30). *H. influenzae* vaccine (Hib Vax), and hepatitis B vaccine should be given as routinely recommended in infancy. Pneumococcal conjugate vaccine is recommended for routine administration as a four-dose series for all children 23 months and younger (PCV7), and a dose of PS23 is recommended to be given at 24 months and an additional dose 3 to 5 years after the first dose. Quadrivalent meningococcal vaccine is recommended for optimal effect at 2 years of age or older. Routine use of yearly influenza vaccine is also recommended.

CONGENITAL PERICARDIAL DEFECTS

Congenital pericardial defects include a wide range of defects varying from minor partial defects to total absence of the pericardium (31).

Van Praagh et al. (21) noted the first report of congenital pericardial defects by Columbus in 1559. Although an uncommon lesion, congenital pericardial defects are difficult to diagnose clinically and often are first recognized at autopsy. Pericardial defects represent defective formation of the pleuropericardial membrane or, if diaphragmatic, defective formation of the septum transversum (32). Most investigators (31) reported left-sided congenital pericardial defects

Figure 53.20. Left-juxtaposed atrial appendages in double-outlet right ventricle (RV). **A:** High left parasternal short-axis scan demonstrating left-juxtaposed atrial appendages in a patient with double-outlet right ventricle. Note the wide base and more bulbous appearance of the right atrial appendage (RAA) located more anteriorly and superiorly. The left atrial appendage (LAA) has a narrow base and finger-like projection. **B:** Parasternal long-axis scan of the same patient demonstrating the pulmonary artery (PA) coursing posteriorly and primarily originating from the anterior RV. Because the right atrium (RA) courses behind the PA in left-juxtaposed atrial appendages, it also separates the pulmonary artery from the mitral valve. A, anterior; Ao, aorta; L, left; LA, left atrium; S, superior; VS, ventricular septum.

as the most common, and the classification by Ellis et al. (33) demonstrated the complete left-sided defect as by far the most common form, representing 56% of their cases. Right-sided, diaphragmatic, and total absence of the pericardium are rare. Approximately one-third of patients with total absence of the

pericardium have associated pulmonary lesions such as bronchogenic cyst or sequestration and congenital heart lesions such as tetralogy of Fallot.

Manifestations

Associated anomalies may dominate the clinical presentation if the pericardial defect is associated with other congenital anomalies such as diaphragmatic hernia or congenital heart disease. Many patients with isolated pericardial defect are asymptomatic. Symptoms, when present, are nonspecific, consisting of vague left chest discomfort, recurrent pulmonary infection, palpitations, and occasionally dizziness and syncope. Partial left-sided pericardial defects may be associated with herniation of the ventricles through the patent pleurop-pericardial foramen, resulting in strangulation of the ventricles and leading to death. Herniation and strangulation of the left atrial appendage also can occur. Obstruction of the SVC can be associated with a right-sided pericardial defect secondary to herniation of the right lung into the pericardial space. Chest pain and the radiographic appearance of cardiomegaly may occur with diaphragmatic pericardial defect, because the associated diaphragmatic defect allows herniation of the greater omentum into the pericardial space.

Diagnosis

Physical examination may yield few abnormal signs. A crescendo-decrescendo systolic murmur at the left sternal border has been attributed to turbulent blood flow with an unusually mobile heart. The apical impulse may be hyperactive and displaced to the left.

The chest radiograph often provides the first clues to the diagnosis. In those with a complete left pericardial defect, the cardiac silhouette is displaced to the left and the left heart border has unusually prominent bulges at the aortic knob, the pulmonary artery, and the LV. There may be insertion of a

Figure 53.21. Atrioventricular override and straddling. Apical four-chamber view in a patient with isolated dextrocardia and severe (type C) straddling of the tricuspid valve in situs solitus, atrioventricular concordance, and dextrocardia. The arrow points to the septal tricuspid leaflet crossing into the left ventricle (LV) with a chordal attachment near the apex. The tricuspid annulus also overrides the ventricular septum (VS) and is partially committed to the LV. L, left; LA, left atrium; RA, right atrium; RV, right ventricle; S, superior.

Figure 53.22. Two-dimensional echocardiographic demonstration of isolated dextrocardia. The subcostal four-chamber view illustrates features similar to those noted in the pathologic specimen of Figure 53.10. There is atrioventricular concordance, with a lower attachment of the right atrioventricular valve along the ventricular septum (VS) consistent with the tricuspid valve (TV). Because of the orientation of the ventricular mass, the atrial septum (AS) assumes a curvilinear shape (white arrow) extending from the right pulmonary veins (PV) to the crest of the VS. (I, inferior; L, left; LA, left atrium; LV, left ventricle; MV, mitral valve; R, right; RA, right atrium; RV, right ventricle; S, superior.)

small portion of the lung between the aorta and the main pulmonary artery or between the left portion of the diaphragm and the inferior border of the heart. A partial left pericardial defect may result in herniation of the left atrial appendage, and there may be prominence of the pulmonary artery segment or the atrial appendage or both. Computed tomography of the chest or magnetic resonance imaging now permit better visualization of absence of the pericardium.

Treatment

Complete absence of the pericardium is usually asymptomatic and is not treated. Only partial forms of pericardial defect (left sided, right sided, or diaphragmatic) require surgical treatment. Surgical treatment of partial pericardial defect has been of two types: enlargement, to avoid the risk of strangulation or closure, usually with a flap of mediastinal pleura. The latter is considered preferable. A defect of the diaphragmatic pericardium requires reduction of the abdominal contents into the abdomen and repair of the diaphragmatic defect.

ECTOPIA CORDIS

Ectopia cordis represents a form of pericardial defect but is further complicated by a partial or complete displacement of the heart outside the thorax. The term ectopia implies an abnormal displacement away from the expected position. A strict interpretation of this term would include any cardiac malposition, such as simple dextrocardia. However, the classic definition of ectopia cordis has represented this entity as a congenital displacement of the heart to a position outside of the thoracic cavity. Kanagasuntheram and Verzin (34) suggested a classification including five types: cervical, thoracocervical,

thoracic, thoracoabdominal, and abdominal. Van Praagh et al. (21) classified ectopia cordis as represented by four types—cervical, thoracic, thoracoabdominal, and abdominal—but suggested that for practical purposes, only two types, thoracic and thoracoabdominal, are clearly represented clinically. Tetralogy of Fallot has been reported in association with the thoracoabdominal form of ectopia cordis.

Cervical forms of ectopia usually are observed with the sternum intact. This form is thought to be rare and may simply represent retention of the heart in its embryonic position in the neck. In the review by Leca et al. (35), they noted 18 cases of cervical ectopia (8.5%), but included some cases with a partial sternal defect.

However, thoracocervical forms of ectopia cordis, with the heart partially in the cervical region and a defect in the superior end of the sternum appear to represent a distinct type of complete ectopia cordis. This form was not included in their review (35) (Fig. 53.23). In this abnormality, the heart is completely outside the thoracic cavity, and there is a complete absence of parietal pericardium and a cephalic orientation of the cardiac apex. No omphalocele or abdominal diastasis was present.

The thoracic type is the classic form of ectopia cordis (21), which is characterized by the following: a sternal cleft allowing protrusion of the heart outside the chest cavity, complete absence of the parietal pericardium, cephalic orientation of the cardiac apex, epigastric omphalocele or diastasis recti, and a small thoracic cavity (Fig. 53.24). The thoracic type occurred in 80 cases (37%) in the review by Leca et al. (35). A small thoracic cavity appears to be a significant etiologic agent as well as having significant implications for successful surgical correction of this defect. Congenital heart disease, most commonly tetralogy of Fallot, but also ventricular hypoplasia, TGA, and double-outlet RV, may be present. Van Praagh et al. (21) also hypothesized that the ruptured amnion syndrome associated with some cases of thoracic ectopia cordis results in oligohydramnios and leads to excessive

Figure 53.23. Thoracocervical ectopia cordis in a 20-week-gestation fetus. There is a defect in the superior portion of the sternum. There is cephalic orientation of the cardiac apex and complete absence of the parietal pericardium. However, there is no omphalocele, and no abdominal visceral anomalies were present. Double-outlet right ventricle and left ventricular hypoplasia were found. Extracardiac defects were also present as evidenced by the bilateral cleft lip and palate. Chromosome analysis was normal. (Provided by Dr. William D. Edwards.)

Figure 53.24. Thoracic ectopia cordis in a newborn infant. There is a sternal defect with complete ectopia cordis. There is cephalic orientation of the cardiac apex and complete absence of the parietal pericardium. There is also a typical epigastric omphalocele. (From Bryon F. Ectopia cordis: report of a case with attempted operative correction. *J Thorac Surg* 1948;17:717, with permission.)

compression of the heart during cardiogenesis, resulting in anterior extrusion of the heart from the chest cavity. Despite this apparent mechanical explanation, chromosomal abnormalities and multiple extracardiac malformations also have been associated with complete thoracic ectopia cordis. Pro-lapse of the forebrain, meningocele, cleft lip, and palate deformities predominated. A defect in the primitive mesenchyme of the body wall also has been proposed as an explanation for ectopia cordis.

Thoracoabdominal ectopia cordis appears to represent a partial form of ectopia cordis. It typically includes the following: partial absence or a cleft of the lower sternum, a crescentic midline anterior diaphragmatic defect, a defect of the diaphragmatic parietal pericardium resulting in a free pericardioperitoneal communication, an omphalocele-like ventral abdominal defect or diastasis recti with partial displacement of the ventricular portion of the heart through the diaphragmatic defect into the epigastrium, and intracardiac congenital heart disease. It has been reported in approximately 37% of cases with ectopia cordis (21). Many different types of congenital heart disease have been reported with thoracoabdominal ectopia cordis including tetralogy of Fallot, double-outlet RV, VSD, ASD, tricuspid atresia, Ebstein anomaly, common atrium, common AV septal defect, anomalous pulmonary venous connections, single-ventricle pulmonary stenosis/atresia, aortic stenosis, coarctation of the aorta, TGA, and diverticulum of the LV or both ventricles. Toyama (36) also reported that at least five cases have had no congenital cardiac malformations.

The abdominal form of ectopia cordis has been extremely rare in some reviews and appears to represent a diaphragmatic defect with continued migration of the heart into the abdominal cavity. In some cases, the patients were apparently healthy, had no other cardiac disease, and died as adults. In the review of Leca et al. (35), 24 cases (11%) were reported to be the abdominal type.

Treatment

Saxena (37) reported the first successful surgical repair of thoracic ectopia cordis. Scott (38) reported the first successful surgical repair of thoracoabdominal ectopia cordis in 1950 by Brock. Repair in this case included repair of the diaphragmatic defect and of the epigastric hernia.

However, most surgical reports have demonstrated poor results for repair of this defect. Nevertheless, due to the complex nature of these malformations and the risk of infection, most have advocated immediate surgery to correct their congenital heart disease and the anterior chest wall defect. Most advocate some form of prosthetic reconstruction of the chest wall and covering the heart with skin. Dobel et al. (39) advised a staged approach with enlargement of the posterior pericardial space by dividing posterior pericardial attachments to the rib margins. Van Praagh et al. (21) advocated avoidance of sepsis, compression, and kinking of the heart. Thus, it was recommended that the cephalic orientation of the ventricular apex not be corrected or altered.

SECTION

VII

Diseases of the Endocardium, Myocardium, and Pericardium

CHAPTER

54

Hypertrophic Cardiomyopathy

Barry J. Maron

Cardiomyopathies, or primary diseases of the myocardium, are not uncommon in infants and children. Although these conditions have been the subject of intensive investigation, our understanding of this diverse group of diseases is constantly evolving with regard to clinical identification, genetics, natural history, and therapy. A contemporary diagnostic classification of cardiomyopathies, including those occurring in young patients, has been proposed through the American Heart Association (AHA) (1).

Hypertrophic cardiomyopathy (HCM) is a genetic cardiac disease with heterogeneous clinical expression, unique pathophysiology, and a diverse natural history caused by >1,400 distinct disease-causing mutations in 11 or more genes encoding proteins of the cardiac sarcomere (1–21). HCM may be diagnosed and cause disability and death at virtually any age, including early childhood and infancy, and notably is the most common cause of sudden death (SD) in young people, including competitive athletes (2–4). Since its modern description almost 50 years ago (8), our understanding of the complexity of HCM has increased dramatically. On the other hand, perhaps no other childhood cardiovascular disease continues to present the challenges and controversies with respect to diagnosis, clinical course, and management as does HCM.

DEFINITION AND NOMENCLATURE

HCM is characterized by a thickened but nondilated left ventricle (LV) in the absence of another cardiac or systemic disease capable of producing the magnitude of hypertrophy

evident (e.g., aortic valve stenosis, systemic hypertension, or some physiologic expressions of athlete's heart) (1–7,22).

In 1958, Donald Teare (8), the coroner of London, published the first modern pathologic report of this disease, in which he described SD in eight young people due to asymmetrical hypertrophy of the ventricular septum (VS). Subsequent investigations led to a dramatic evolution in our perceptions of the HCM clinical spectrum. In the process, the disease acquired a confusing array of names, all presumably describing the same clinical entity. Most of these terms used to describe HCM emphasized LV outflow obstruction. Thus, the names "idiopathic hypertrophic subaortic stenosis," "hypertrophic obstructive cardiomyopathy," and "muscular subaortic stenosis" (as well as their abbreviations: IHSS, HOCM, and MSS) became widely used. However, about one-third of patients with HCM have either no or only mild obstruction to LV outflow at rest or with exercise (2,3,23). Hence, the preferred name for this condition has become *hypertrophic cardiomyopathy* (with or without obstruction). However, it is potentially confusing to apply this term to describe systemic, metabolic, or multiorgan syndromes associated with increased LV wall thickness (21).

PREVALENCE

Several epidemiologic studies are now available showing that HCM is the most common of the genetic heart diseases occurring in at least 1:500 of the general population (2,24,25). This overall prevalence is disproportionate to the numerical recognition of HCM in clinical cardiology practice (26),

particularly pediatric cardiology. HCM is a global disease now reported from >50 countries (27), with the most intense interest and reporting of cases from North America, Western Europe, Africa, and Asia (Japan and China).

MORPHOLOGY

Left Ventricular Hypertrophy

Multiple echocardiographic studies have defined the gross morphologic features of HCM, particularly its pronounced diversity and myriad patterns of LV hypertrophy (LVH) (2,3,6,7,9–18,28–30) (Figs. 54.1–54.4). Indeed, in HCM, there is no single or classic morphologic form, and virtually all possible patterns of LVH have been observed. Even closely related relatives with the same genetic substrate usually have dissimilar patterns of LVH with the exception of identical twins in whom the hearts appear identical. Although a truly symmetric (concentric) pattern of LVH may occur occasionally (6) (Fig. 54.2), the distribution of wall thickening in HCM is characteristically asymmetric, in which ≥ 1 segment of the wall shows greater hypertrophy than other areas (6,7,28–30). Frequently, the pattern of hypertrophy is particularly heterogeneous, with contiguous segments of the LV wall differing greatly in thickness (7).

Clinical diagnosis of HCM is usually made with 2-D echocardiography (6) or cardiovascular magnetic resonance (CMR) imaging (7). CMR may be advantageous by visualizing areas of segmental hypertrophy, specifically in the anterolateral free wall and LV apex, not always reliably identifiable with echocardiography (Fig. 54.3) (7,28,29).

Hypertrophy may be diffuse and involve substantial portions of VS and LV free wall, including the most substantial hypertrophy observed in any cardiac disease, with wall thicknesses ranging up to 5 to 6 cm (6,7,12,29), and often three to five times normal (Figs. 54.1–54.4). However, notably, in about one-third of HCM patients, LVH is relatively mild (13) and confined to limited areas of the LV wall, that is, usually basal anterior septum, but less frequently the apex, posterior portion of septum, and anterolateral or posterior free wall (6,7,28–30) (Figs. 54.1–54.3).

Segmental wall thickening confined to the LV apex (Fig. 54.2), a form of HCM more commonly reported from Japan, is associated with a “spade” deformity of the distal LV and striking T-wave inversion and increased R-wave voltages in the lateral precordial leads on ECG (15–17,31). However, it should be underscored that asymmetric patterns of LVH are not unique to HCM and may also be observed in systemic hypertension and in children and adults associated with other congenital or acquired heart diseases, including those with pulmonary arterial hypertension (1). Notably, based on genotype–phenotype studies in HCM families, genetically affected relatives may nevertheless have normal LV wall thicknesses (a subgroup referred to as genotype positive/phenotype negative) (32). Therefore, any absolute LV wall thickness is compatible with HCM.

Serial echocardiographic investigations have shown that LVH in HCM is not usually present at birth, but commonly develops in a dynamic fashion after a period of prolonged latency (33–36). Typically, the HCM phenotype (i.e., LVH) is not complete until adulthood, and during adolescence when body growth accelerates, genetically affected patients often show striking spontaneous increases in wall thickness (i.e., by an average of 100%) and more extensive distribution of hypertrophy (33) (Fig. 54.4). These dynamically evolving changes in LVH occurring during adolescence appear to be part of the genetically predetermined morphologic expression of HCM and are not per se associated with development or progression of symptoms or cardiac events. Mitral valve

systolic anterior motion (SAM) and outflow obstruction may also develop in childhood, during the period of progressive LVH, and in the presence of a developmentally small outflow tract (35). Of note, in genetically affected children, 12-lead ECG abnormalities may be the initial clinical manifestation of the disease, even preceding appearance of LVH on 2-D echocardiogram or CMR (34,36) (Fig. 54.4).

Mitral Valve

Structural abnormalities of the mitral valve, characteristic of many patients with LV outflow obstruction, may also be regarded as primary features of HCM (37,38). The majority of patients studied at necropsy (37) or by CMR (38) show important alterations in mitral valve size and shape. These primary abnormalities include increased overall mitral leaflet area (up to twice normal) owing largely to elongation of the leaflets (37) and, with considerable diversity, an increased size of both anterior and posterior leaflets.

Secondary thickening of the anterior mitral leaflet may result from frequent contact with the VS, associated with localized endocardial thickening of the septum in the LV outflow tract adjacent to the anterior leaflet. Endocardial plaques on ventricular septum occur most commonly in the presence of LV outflow obstruction (due to mitral valve–septal systolic contact), but may also develop in nonobstructive HCM due to diastolic mitral valve–septal contact.

Histopathology

Cardiac muscle cells (myocytes) in VS and LV free wall have increased transverse diameter as well as bizarre shapes, often maintaining intercellular connections with several adjacent cells (39–43). Of note, many of these myocytes do not show normal parallel alignment, but are arranged in a chaotic, disorganized fashion at oblique and perpendicular angles to each other (Fig. 54.3); myofibrils within cardiac muscle cells may also show disarray. Areas of disorganized cardiac muscle cells are found in about 95% of patients dying of HCM and usually occupy substantial portions of LV myocardium, that is, about 33% of septum and 25% of free wall (39,43). Disorganized myocytes are not confined to markedly thickened segments of the wall but can also be present in nonhypertrophied areas of the LV, and with little relationship evident between the magnitude of wall thickening and extent of disarray (41). The finding of marked cellular disorganization in a few symptomatic infants with HCM suggests that this histologic abnormality can be present from birth (42).

It is likely that disorganized cells dispersed in the LV wall impair transmission of normal electrophysiologic impulses and predispose to disordered patterns and increased dispersion of electrical depolarization and repolarization. Therefore, this chaotic architecture may well serve as an electrically unstable arrhythmogenic substrate and the nidus for potentially lethal ventricular tachyarrhythmias and SD in HCM or as a determinant of LV diastolic or systolic dysfunction.

Abnormalities of intramural coronary arteries (i.e., “small vessel disease”) are present in about 80% of patients studied at necropsy, most commonly in VS (44,45) (Fig. 54.3). These vessels are characterized by thickening of the arterial wall with increased intimal or medial components and apparent narrowing of the lumen. The abnormal arterioles may be responsible for silent myocardial ischemia and are most frequently observed within or in close proximity to areas of replacement fibrosis. HCM patients show variable severity and distribution of such fibrous tissue formation within LV myocardium, including patchy replacement fibrosis and grossly visible scars

FIGURE 54.1. Morphologic components of the underlying disease process in HCM. **A:** A gross heart specimen sectioned in a cross-sectional plane similar to that of the echocardiographic (parasternal) long axis showing a common pattern of asymmetric LVH with wall thickening confined primarily to the AVS, which bulges prominently into the left ventricular outflow tract. LV denotes left ventricular free wall. **B:** A heart specimen in the transverse cross-sectional plane with a different pattern of hypertrophy; here, marked LV wall thickening is also asymmetric but predominantly in the PVS, whereas the AVS is only minimally thickened. **C,D:** Histology characteristic of the LV in HCM. **C:** The septal myocardium shows a markedly disordered architecture with adjacent hypertrophied cardiac muscle cells arranged at perpendicular and oblique angles. **D:** Bundles of hypertrophied cells show a disorganized, interwoven arrangement. **E:** An intramural coronary artery with an apparently narrowed lumen and thickened wall owing primarily to medial (M) hypertrophy. **F:** Extensive scarring of ventricular septum that is transmural in distribution, characteristic of the end-stage phase. LV, left ventricle; AVS, anterior ventricular septum; PVS, posterior ventricular septum; VS, ventricular septum. (From Maron BJ, Bonow RO, Cannon RO, et al. Hypertrophic cardiomyopathy. Interrelations of clinical manifestations, pathophysiology, and therapy. *N Engl J Med* 1987;316:780, with permission of Massachusetts Medical Society.)

FIGURE 54.2. Patterns of LVH in HCM. Heterogeneous distribution and extent of LV wall thickening by echocardiography. **A:** Massive asymmetrical hypertrophy of VS with thickness >50 mm. **B:** Septal hypertrophy with distal portion considerably thicker than proximal region. **C:** Hypertrophy confined to proximal septum just below aortic valve (arrows); **D:** Hypertrophy localized to LV apex (asterisk)—that is, “apical HCM”; **E:** Relatively mild hypertrophy in symmetrical pattern showing similar or identical thicknesses within each segment (paired arrows); **F:** Inverted pattern with posterior free wall (PW) thicker (40 mm) than anterior VS. Calibration marks = 1 cm. Ao, aorta; AML, anterior mitral leaflet; LA, left atrium. (Reproduced from, Maron MS, Maron BJ, Harrigan C, et al. Hypertrophic cardiomyopathy phenotype revisited after 50 years with cardiovascular magnetic resonance. *J Am Coll Cardiol* 2009;54:220–228, with permission of Elsevier).

FIGURE 54.3. CMR identification of segmental LV wall thickening in HCM. Diagnosis. Two-dimensional echocardiogram (A) and comparative CMR (B) images acquired in short-axis plane at end-diastole at the same level from 13-year-old asymptomatic identical twin. A: Echocardiogram shows normal anterolateral free wall thickness (asterisks). B: CMR shows segmental area of hypertrophy confined to anterolateral LV free wall (20 mm) and small portion of contiguous anterior septum. Calibration marks are 1 cm apart. (Reproduced from Maron MS, Maron BJ, Harrigan C, et al. Hypertrophic cardiomyopathy phenotype revisited after 50 years with cardiovascular magnetic resonance. *J Am Coll Cardiol* 2009;54:220–228, with permission of AHA). Echocardiogram (C) and comparative CMR (D) from 46-year-old man with HCM. C: Echocardiographic short-axis shows anterolateral free wall thickness of 18 mm. D: CMR shows focal area of massive LVH (wall thickness, 35 mm) in the same region of LV, significantly underestimated by 2-D echocardiography. CMR finding defined high-risk status, prompting altered management strategy with an ICD recommendation for primary prevention of SD. Calibration markers are 1 cm apart. RV, right ventricle. (Reproduced from, Maron MS, Maron BJ, Harrigan C, et al. Hypertrophic cardiomyopathy phenotype revisited after 50 years with cardiovascular magnetic resonance. *J Am Coll Cardiol* 2009;54:220–228, with permission of Elsevier).

FIGURE 54.4. LV remodeling with development or progression of HCM phenotype. **Left:** Childhood/adolescence. Increased echocardiographic LV wall thickness in patients with familial HCM, unassociated with changes in clinical course. Open symbols denote those without initial evidence of hypertrophy in any LV segment. (Reproduced from Maron BJ, Spirito P, Wesley Y, et al. Development and progression of left ventricular hypertrophy in children with hypertrophic cardiomyopathy. *N Engl J Med* 1986;315:610–614, with permission of Massachusetts Medical Society). **Right:** Adulthood. Woman with myosin-binding protein C mutation shown at age 30 years with normal LV thickness (≤ 12 mm) in all segments of the wall (Top); 6 years later, at age 36, wall thickness has increased to 20 mm in both anterior ventricular septum and posterior septum, as well as anterolateral free wall. Bottom: LV wall thickness eventually increased to >30 mm, and the patient was prophylactically implanted with a defibrillator for primary prevention of SD. Calibration marks are 10 mm apart. VS, ventricular septum. (Reproduced from Maron BJ, Niimura H, Casey SA, et al. Development of left ventricular hypertrophy in adults with hypertrophic cardiomyopathy caused by cardiac myosin-binding protein C mutations. *J Am Coll Cardiol* 2001;38:315–321, with permission of Elsevier).

that may be extensive or even transmural, representing a repair process following myocyte death (44–49) (Fig. 54.3). This myocardial fibrosis, long recognized at autopsy (48), can now be identified in vivo with contrast CMR (50). In addition, the interstitial (matrix) collagen compartment, constituting the structural framework of LV is substantially increased in size; its components (perimysial coils, pericellular weaves and struts) are increased in number, appear morphologically abnormal, and often show disorganized arrangement (49).

Taken together, these findings suggest a form of small-vessel disease that may be responsible for silent myocardial ischemia, necrosis, and ultimately replacement fibrosis in HCM (51–55). Areas of myocardial fibrosis and scar can be responsible for LV systolic dysfunction (i.e., end-stage HCM) (56) and/or represent a substrate for clinically important ventricular tachyarrhythmias (57,58).

PATHOPHYSIOLOGY

Left Ventricular Outflow Obstruction

The presence of LV outflow tract obstruction under basal conditions (gradient ≥ 30 mm Hg) over many years is a

determinant of progressive heart failure symptoms and cardiovascular death in HCM (59) (Fig. 54.5). The relationship of obstruction specifically to sudden cardiac death is much weaker, encumbered by particularly low positive-predictive value (59). Obstruction in HCM represents true mechanical impedance to LV outflow, producing markedly increased intraventricular pressures, which can be detrimental to LV function by increasing myocardial wall stress and oxygen demand.

Dynamic subaortic obstruction in HCM is usually produced by the mitral valve, causing contact between the mitral valve and VS (SAM). Characteristic of young patients with this disease is an abrupt anterior motion in which the elongated mitral valve leaflets move toward (or contact) the VS in early systole (with a 90-degree sharp-angled bend). Magnitude of the outflow gradient is directly related to duration of mitral-septal contact with prolonged contact throughout midsystole indicative of marked obstruction. Estimation of the magnitude of outflow obstruction is made conventionally with continuous wave Doppler (60), which obviates the need for diagnostic cardiac catheterization.

SAM and subaortic obstruction are determined by several geometric factors including the size of the outflow tract, distribution of LVH, and length of the mitral leaflets (37,61,62) as well as the ejection velocity. SAM appears to occur either by virtue of the high-velocity jet streaming through a narrowed outflow tract

FIGURE 54.5. Left ventricular outflow tract obstruction. **A:** Probability of severe progressive heart failure (NYHA classes III or IV), heart failure death, or stroke in patients with LV outflow obstruction exceeds that in patients without obstruction (relative risk, 4.4; $p < 0.001$). (Reproduced from Maron MS, Olivotto I, Betocchi S, et al. Effect of left ventricular outflow tract obstruction on clinical outcome in hypertrophic cardiomyopathy. *N Engl J Med* 2003;348:295–303, with permission of Massachusetts Medical Society). **B:** Changes in LV outflow tract gradient from resting (basal) conditions to immediately after termination of treadmill exercise. Each patient is depicted by a line connecting the two gradient measurements. θ indicates the mean. (Reproduced from Maron MS, Olivotto I, Zenovich AG, et al. Hypertrophic cardiomyopathy is predominantly a disease of left ventricular outflow tract obstruction. *Circulation* 2006;114:2232–2239, with permission of AHA.) **C:** Following myectomy with relief of LV outflow obstruction, survival free from all-cause mortality compared with age- and gender-matched U.S. population and also nonoperated patients with obstruction ($p < 0.001$). (Reproduced from Ommen SR, Maron BJ, Olivotto I, et al. Long-term effects of surgical septal myectomy on survival in patients with obstructive hypertrophic cardiomyopathy. *J Am Coll Cardiol* 2005;46:470–476, with permission of Elsevier.)

and pulling the mitral leaflets toward the septum (i.e., Venturi effect) or probably more likely due to drag (the hydrodynamic pushing force of flow) on the leaflets (63). The posteriorly directed mitral regurgitation jet, as a consequence of SAM, is usually only mild to moderate; severe mitral regurgitation in an HCM patient should raise the possibility of an intrinsic mitral valve abnormality such as myxomatous degeneration (64).

The subaortic gradient (and systolic ejection heart murmur) in HCM is characteristically dynamic (65) and may show considerable spontaneous variability, that is, reduced or abolished by interventions that decrease myocardial contractility (e.g., β -adrenergic receptor blocking drugs) or increase ventricular volume or arterial pressure (e.g., squatting, isometric hand-grip, or phenylephrine administration). Alternatively, the outflow gradient and murmur can be augmented by circumstances that decrease arterial pressure or ventricular volume (e.g., the Valsalva maneuver or administration of nitroglycerin) or that increase contractility, such as premature ventricular contraction, standing, amyl nitrite inhalation, administration of isoproterenol, or exercise (2–4,65). Daily activities such as consuming a heavy meal may also transiently magnify the subaortic gradient (2,3). A large proportion of HCM patients without SAM or gradients at rest may nevertheless generate outflow obstruction with physiologic exercise. Indeed, fully 70% of an HCM cohort may have the propensity to develop obstruction (gradient ≥ 30 mm Hg) either at rest or with exercise (Fig. 54.5) (23).

In infants and young children with HCM, obstruction to right ventricular outflow is not uncommon, usually occurring in association with subaortic obstruction. Subpulmonic gradients represent a form of fixed obstruction due to exaggerated hypertrophy of right ventricular musculature that projects into the relatively small outflow tract (i.e., crista supraventricularis muscle, papillary muscles, moderator band, or trabeculae) (66). The infrequency of subpulmonic obstruction in adult HCM patients suggests that these gradients probably disappear with body growth and cardiac remodeling.

Myocardial Ischemia

Regional myocardial ischemia (in the absence of atherosclerotic coronary artery disease) occurs commonly in HCM (51–54,67), as demonstrated by atrial pacing, reversible exercise-induced myocardial perfusion defects, dipyridamole stress ECG, necrosis, and replacement fibrosis observed at autopsy or by CMR imaging (as delayed enhancement), or abnormalities recognized by position emission tomography (PET) (54,67). Potential mechanisms by which myocardial ischemia may occur in HCM include inadequate capillary density compared with greatly increased LV muscle mass, or alternatively, small vessel disease with narrowed intramural coronary arteries (44,45). It is difficult to clinically measure and quantitate the extent or location of myocardial ischemia in HCM patients, or consistently derive relevant correlations or prognostic information from these observations, although observations with PET suggest ischemia is a determinant of progressive heart failure in HCM (67).

Diastolic Dysfunction

Abnormalities of LV relaxation and filling have been identified by a variety of echocardiographic-Doppler methods in a majority of patients with HCM and presumably contribute to (or are responsible for) symptoms of fatigue, exertional dyspnea, and angina pectoris (2,3,5,68–74). The rapid filling phase of diastole is significantly prolonged and associated with decreased rate and volume compared with normal. Consequently, there is usually a compensatory increase in the

contribution of atrial systole to overall LV filling. Conversely, diastolic dysfunction may be present in the absence of both symptoms and outflow obstruction and unrelated to the severity or distribution of ventricular hypertrophy (70). Reduced ventricular distensibility probably results largely from those factors, which determine the passive elastic properties of the LV chamber, such as severity of hypertrophy, replacement and interstitial myocardial fibrosis, and cardiac muscle cell disorganization.

GENETICS

The capability of achieving an unequivocal diagnosis of HCM with DNA-based laboratory methods has led to enhanced recognition of HCM and consequently to a more complete definition of its broad clinical spectrum, as well as providing practical insights into appropriate genetic counseling (1–3,19,20,75–79).

HCM is a Mendelian trait with an autosomal dominant pattern of inheritance (1,19,20,75,80,81). Molecular studies with clinical genotype–phenotype correlations, conducted intensively over more than a decade, have provided important insights into the genetics of HCM, as well as access to definitive laboratory-based diagnosis by virtue of detecting pathogenic mutations, even in the absence of obvious clinical evidence of the disease. This substantial investigative effort has demonstrated convincingly that HCM is caused by dominant mutations in 11 or more genes encoding thick and thin contractile myofilament protein components of the sarcomere and the adjacent Z-disc. Several additional mutations have also been identified but are associated with less definitive evidence to support their pathogenicity. About 70% of the HCM mutations are reported in the two most common genes, β -myosin heavy chain and myosin-binding protein C, while troponin T and several other genes account for much smaller proportions. Underscoring the vast genetic heterogeneity of HCM, over the last 20 years >1,400 individual mutations (mostly missense, but also insertions, deletions, splice, and truncated mutations) have been identified among these genes, with about two-thirds unique to individual families when first identified (i.e., “private”).

The vast majority of patients who inherit a disease-causing mutation will demonstrate structural evidence of HCM (i.e., LVH) by early adulthood, appearing typically during periods of accelerated adolescent growth and usually completed when physical maturity is achieved (age 17 to 18 years), but generally unassociated with symptom onset or disease progression (33). However, variable and age-related penetrance can occasionally result in delayed expression of the phenotype into the third decade of life, or potentially even later (77).

Development of rapid, automated DNA sequencing now provides the opportunity for comprehensive genetic testing panels, which permit identification of HCM mutations and definitive molecular diagnosis as part of routine clinical practice (19,77–79,80,81). However, disease-causing mutations can be identified definitively in only about one third of those probands studied, underscoring that all genes that cause HCM are not known. Therefore, the precise mutation responsible for HCM remains uncertain in a significant proportion of patients. In addition, not uncommonly, DNA-based testing may identify novel DNA sequence variants for which true pathogenicity is unresolved (“variants of uncertain significance”) (80,81).

Despite these limitations, the most important role of DNA molecular testing is to identify HCM family members at risk for developing disease who do not have LV hypertrophy. If a disease-causing mutation can be identified in a phenotypically expressed relative with HCM, the genetic status

FIGURE 54.6. LAMP2 cardiomyopathy. **A:** From 14-year-old boy with SD and septal thickness of 65 mm (heart weight 1,425 g); **B:** Clusters of myocytes with vacuolated sarcoplasm (stained red) embedded in area of scar (stained blue; Masson trichrome). **C:** Disorganized arrangement of myocytes most typical of sarcomeric HCM. **D:** Intracardiac electrogram. ICD elicited five defibrillation shocks that failed to interrupt VF (280 beats/min). (Reproduced from Maron BJ, Roberts WC, Arad M, et al. Clinical outcome and phenotypic expression in LAMP2 cardiomyopathy. *JAMA* 2009;301:1253–1259, with permission of American Medical Association.)

of other members of the family can be determined definitively. In addition, genetic testing has the potential to clarify diagnosis in patients for whom the pattern of LVH mimics HCM, for example, metabolic storage disease phenocopies: PRKAG2 (regulatory subunit of adenosine monophosphate-activated protein kinase); Fabry disease (alpha-galactosidase deficiency), and LAMP2 (Danon disease; lysosome-associated membrane protein-2) (82,83) (Fig. 54.6). Genetic diagnosis of Fabry disease is highly advantageous, given the availability of enzyme replacement therapy (84). LAMP2 cardiomyopathy is associated with severe and lethal natural history with survival uncommon over 25 years of age (and implantable defibrillators [ICDs] are unreliable), requiring early recognition by genetic testing to permit timely consideration for prophylactic heart transplant (83) (Fig. 54.6).

However, after two decades of the molecular era and many genotype–phenotype correlation studies, the overall relationship between single sarcomere mutations and prognosis or clinical outcome in HCM has proved unreliable, due largely to genetic heterogeneity, disputing earlier notions that specific mutations would have prognostic relevance (i.e., “malignant” or “benign” mutations) (80,81,85). Therefore, despite considerable initial optimism and perhaps the unrealistic expectation that the discipline of molecular biology would create a new paradigm for predicting prognosis and directing management in HCM, this aspiration has been largely unrealized. Nevertheless, preliminary data suggest that double or compound sarcomere mutations (present in about 5% of HCM patients) may be associated with greater disease severity and adverse events (86).

It is presently unknown what proportion of mutation carriers (gene positive–phenotype negative family members without hypertrophy) will ultimately develop LVH, but the risk for SD (or disease progression) in this subset appears particularly low (32). At present, clinical decisions regarding disqualification from competitive sports or occasionally consideration for prophylactic ICDs (74) in such individual are unavoidably made on a case-by-case basis (32). This emerging patient subset will require much longer periods of follow-up before reliable guidelines regarding management can be formulated.

CLINICAL SCREENING STRATEGIES IN FAMILIES

In clinical practice, prospective screening of HCM family members to ascertain affected or unaffected disease status usually takes place independent of genetic testing and is performed primarily with 2-D echocardiography, CMR, and ECG, as well as history-taking and physical examination (20).

The traditional recommended strategy for screening relatives in most HCM families calls for such evaluations on a 12- to 18-month basis, usually beginning at least by age 12 (20). If these studies do not show evidence of LVH by the time full growth is achieved (at the age of about 18 to 21 years), it had been customary practice to conclude that a HCM-mutant gene is probably absent and reassure family members accordingly that further echocardiographic testing would be unnecessary. However, recognition of the possibility that later-onset morphologic conversions to the HCM phenotype may occur in young and middle-aged adults (and even older individuals) has potentially created new practice strategies for screening families and genetic counseling in this disease (2,20,77) (Table 54.1). Therefore, it is no longer possible to routinely hold to the traditional tenet that a normal echocardiogram (and ECG) obtained at maturity itself defines a genetically unaffected

family member. It is now probably prudent to extend the time period into adulthood for clinical surveillance of phenotype-negative relatives at about 5-year intervals with serial 2-D echocardiography or CMR, and ECG (20).

While this recommendation (triggered by the recognized potential for adult-onset hypertrophy) is probably unavoidable in current clinical practice, there are nevertheless potentially negative implications for this strategy. By extending almost indefinitely the period of morphologic (i.e., echocardiographic) surveillance and implied indecision regarding the diagnosis of HCM in family members, there is the potential risk of eliciting the psychological perception and stigma of cardiac disease in young, healthy individuals, the vast majority of whom are not in fact affected by a mutant gene. If the causative HCM gene is identified in a family member, molecular testing can be definitive by excluding affected status and thereby eliminating the need for serial clinical studies and prolonged surveillance.

CLINICAL FEATURES

Physical Examination

The classic findings on physical examination in patients with HCM are variable and related in large measure to hemodynamic state (65). For example, in patients with obstruction to outflow, a double or triple LV apical impulse may be palpable. These impulses probably reflect the usual outward systolic thrust due to ventricular contraction, a presystolic thrust of accentuated atrial contraction, and occasionally the expansion of early diastolic filling. In addition, patients with obstruction have a medium-pitch systolic ejection murmur that varies in intensity with respect to the magnitude of the subaortic gradient. Patients with loud systolic murmurs along the lower left sternal border and at the apex of at least grade 3/6 in intensity will probably have a peak systolic gradient >50 mm Hg. In some patients, the murmur may sound holosystolic at the apex and mimic mitral regurgitation. In the presence of outflow obstruction, the arterial pulses are unusually sharp and rapid rising with a distinct Bisferiens contour. External carotid pulse recordings demonstrate a bifid pulse contour, shortened upstroke time, and increased systolic ejection period. Indeed, infants and young children with HCM are most commonly identified because of a heart murmur or vigorous precordial thrust, with a diagnosis subsequently confirmed by imaging (87–92).

In contrast, physical findings in HCM patients without outflow obstruction may be subtle and not suggestive of underlying heart disease. The systolic murmur is characteristically soft or absent, although the LV apical impulse may nevertheless be forceful. In some patients, a murmur representing dynamic outflow obstruction may be provoked by standing, or with the Valsalva maneuver.

Symptoms

The onset of heart-failure symptoms often occurs in early adulthood, between 20 and 40 years of age, although symptoms can become evident at any age, from young children to the elderly (2). Nevertheless, it is uncommon for children or adolescents to experience marked progressive functional disability equivalent to New York Heart Association (NYHA) class III. In most patients, the predominant complaint is exertional limitation due to heart failure-related symptoms such as dyspnea and/or fatigue and also occasionally orthopnea or paroxysmal nocturnal dyspnea (very uncommon in children),

TABLE 54.1
Proposed Clinical Family Screening Strategies with Echocardiography or CMR (and 12-lead ECG) for Detection of HCM with LVH

Age ≤12 y
Optional unless
Malignant family history of premature death from HCM, or other adverse complications
Competitive athlete in an intense training program
Onset of symptoms
Other clinical suspicion or early LVH
Age 12 to 18–21 y*
Every 12–18 months
Age ≥ 21 years
At onset of symptoms or possibly every 5 years. More frequent intervals are appropriate in families with a malignant clinical course or late-onset HCM

*Age range takes into consideration individual variability in achieving physical maturity and in some patients may justify screening at an earlier age. Initial evaluation should occur no later than early pubescence.

which may be accompanied by chest discomfort that is either typical or atypical of angina. The etiology of chest pain in HCM is not completely understood, but may be a manifestation of myocardial ischemia due to microvascular structural abnormalities (44,54). Severity and character of these symptoms may be similar in patients with or without obstruction to LV outflow. Episodes of impaired consciousness (syncope/presyncope/near syncope) are common and may raise consideration of SD risk.

Electrocardiogram

The 12-lead ECG is abnormal in about 90% to 95% of HCM probands identified as part of hospital-based populations and shows a wide variety of abnormal patterns, some of which may be bizarre in appearance (31,93–95). Normal ECGs are much more common in asymptomatic family members recognized during pedigree screening (up to 25%). Most common ECG abnormalities are increased voltages suggestive of LVH, ST-T changes including marked T-wave inversion in the lateral precordial leads, left atrial enlargement, deep and narrow Q waves, and diminished R waves in the lateral precordial leads.

However, no particular ECG pattern is characteristic of HCM or predictive of future events (94), although normal ECGs appear to be most commonly associated with benign clinical course (95). Increased voltages (tall R or deep S waves) show only a weak correlation with magnitude of LVH by echocardiography and do not discriminate the presence or absence of outflow obstruction at rest (94). Paradoxically, infants with HCM often show a pattern of right ventricular hypertrophy, which only in some cases may reflect obstruction to right ventricular outflow (66,87).

HCM AND ATHLETE'S HEART

Long-term athletic training can produce increases in LV diastolic cavity dimension, wall thickness, and calculated mass that constitute a syndrome commonly known as “athlete’s heart” (22,96–98). Such absolute increases in LV wall thickness are usually modest, but may be more substantial in some athletes, particularly those participating in the rowing and cycling sports (97). In this way, a diagnostic dilemma in distinguishing the clinically benign physiologic hypertrophy of the athlete’s heart from HCM (with relatively mild LVH) may arise (22,96). Several clinical parameters have been suggested to aid this differential diagnosis (Fig. 54.7). Some useful criteria that support the diagnosis of HCM in trained athletes who fall into the “gray zone” of overlap between the two conditions with maximum LV wall thickness of 13 to 15 mm include (22,96) demonstration of a HCM disease-causing mutation with genetic testing, documentation of HCM in a relative, an abnormal transmitral Doppler waveform consistent with altered LV relaxation and filling, or LV end-diastolic cavity dimension <45 mm. Parameters favoring athlete’s heart include regression of LV wall thickness following a brief (4 to 8 weeks) period of deconditioning and LV end-diastolic cavity dimension >55 mm.

PREPARTICIPATION SCREENING FOR HCM IN ATHLETIC POPULATIONS

Detection of preexisting cardiovascular abnormalities such as HCM, with the potential for SD or significant morbidity associated with intense physical training and competition, is

FIGURE 54.7. Differential diagnosis of HCM versus physiologic athlete’s heart. Clinical criteria used to distinguish non-obstructive HCM from athlete’s heart when maximal LV wall thickness is within the shaded gray area of overlap, consistent with both diagnoses. ↓, decreased. (Adapted from, Maron BJ, Pelliccia A. The heart of trained athletes: cardiac remodeling and the risks of sports, including sudden death. *Circulation* 2006;114:1633–1644, reproduced with permission of AHA.)

a major objective of preparticipation screening of high school and college-aged sports participants (99–101). In the United States, customary screening practice dictates that a personal and family history be obtained and a physical examination performed. However, although HCM can be identified by this process, in some cases, the disease remains unsuspected, given that many affected individuals do not have a diagnostic heart murmur or historical clues (e.g., syncope or family history of HCM). It has been suggested that identification of HCM by screening would theoretically be enhanced by routinely incorporating noninvasive testing with the 12-lead ECG (or echocardiography) (102). However, cost-effectiveness and a number of resource and practical obstacles make routine application of such tests impractical as part of a theoretical mandated and nationally administered (and federally funded)

mass screening program of U.S. athletes (99). Frequency of borderline and false-positive (or false-negative) test results, and the uncertainty and anxiety that accompanies such circumstances, represent additional limitations to high school screening programs with routine ECGs (99).

CLINICAL COURSE

Overall Patient Population

Predicting the clinical course and outcome for individual young patients with HCM continues to be difficult because of the marked variability and heterogeneity in disease expression. For patients first identified in the pediatric age group, accurate predictions regarding natural history and prognosis are particularly daunting given the particularly long period (>50 years) of potential risk that lies ahead. Annual HCM mortality rates have previously been reported at 3% to 6%, with the highest rate in children (103,104). However, these are now outdated estimates derived largely from HCM cohorts at major HCM referral centers, incorporating substantial patient selection bias skewed toward high-risk patients (105). Therefore, highly selective referral patterns have previously overestimated and mischaracterized the risk for premature death in the overall HCM population. Over the more recent 15 years, in unselected community-based patient populations less contaminated by tertiary center referral basis (and therefore more representative of the true disease state), more realistic mortality rates for HCM of about 1% per year have been reported, although somewhat higher in children (i.e., 2% per year) (2,3,106–109).

The clinical dilemma encountered in pediatric cardiology practice with respect to HCM is unique, given the youth of the patients and the difficulties encountered in predicting outcome for such a heterogeneous disease over long periods. This is compounded by the fact that most children who die suddenly have previously been asymptomatic (or only mildly symptomatic), and such catastrophes are often the first clinical manifestation of the disease (2,3). On the other hand, it is inappropriate to regard all patients identified with HCM in infancy and childhood as having an ominous prognosis simply by virtue of diagnosis early in life, particularly since most such clinical identifications are made under fortuitous circumstances.

Thus, HCM should be viewed as a complex disorder capable of producing important clinical consequences and premature death in some patients, whereas many other patients may live their natural lives (even achieve statistical life expectancy) with little or no disability and do not require aggressive therapeutic interventions. These observations emphasize the importance of providing many HCM patients (including many children) with reassurance regarding their prognosis, but also with prudent caution and long-term regular surveillance, for what is also an unpredictable disease.

Infants

Experience with assessing the clinical course and prognosis of patients with HCM identified in the first 2 years of life has been limited. Relatively few patients considered to have HCM are reported so early in life (87–92), and a large proportion of such infants with LVH do not have true familial HCM caused by mutations in genes encoding sarcomere proteins (1). Such HCM phenocopies include Noonan syndrome, glycogen storage disease, or a transient and nonfamilial cardiomyopathy in infants of insulin-dependent diabetic mothers with generalized organomegaly (1).

Other diseases in this category are primary mitochondrial myopathies caused by mutations encoding mitochondrial DNA (e.g., Kearns-Sayre syndrome) or mitochondrial proteins associated with adenosine triphosphate (ATP) electron transport chain enzyme defects (1). Also included in these considerations are metabolic myopathies representing ATP production and utilization defects involving abnormalities of fatty acid oxidation (acyl CoA dehydrogenase deficiencies) and carnitine deficiency, as well as infiltrative myopathies such as Hunter and Hurler diseases (1).

HCM is a particularly uncommon cause of SD during infancy and is not a cause of the sudden infant death syndrome (110). Nevertheless, the onset of symptoms and heart failure in infancy or early childhood appears to be an unfavorable prognostic sign indicative of early disease progression (87,89,103) with high mortality in the ensuing months or years from heart failure, despite aggressive surgical and/or medical therapy. Reports of spontaneous regression of LVH and resolution of heart failure within the first few months of life appear to be virtually confined to infants of diabetic mothers.

Children

Prognostic assessment of children with HCM is also limited by the low frequency with which such patients are identified in standard pediatric practice, and the relatively brief period of their life time they are followed. Most HCM patients recognized as children and adolescents are asymptomatic, and it is uncommon for severe functional disability, such as with NYHA class III, to appear at this time in life. Nevertheless, HCM-related mortality has consistently been reported to be highest in HCM patients identified as children or adolescents, with most of these deaths occurring suddenly and unexpectedly (89,92,109,111–114).

Noonan syndrome, an autosomal dominant cardiofacial condition, can mimic sarcomeric HCM. In about 50% of cases, Noonan syndrome is familial with an autosomal dominant transmission, caused by mutations in PTPN11, a gene encoding the nonreceptor protein tyrosine phosphatase SHP-2 genes (1). Noonan syndrome deserves special emphasis here because of the frequency with which LVH occurs (about 25% of such patients). There is also frequent association with other congenital heart malformations, the most common of which is dysplastic pulmonary valve stenosis and atrial septal defect. Cardiomyopathies characterized by LV wall thickening have also occasionally been reported in young children with other systemic diseases: neuroectodermal anomalies, pheochromocytoma, tuberous sclerosis, neurofibromatosis, lentiginosis, Friedreich ataxia, Turner syndrome, and hyperthyroidism (1). It is more likely that such infrequent associations represent only the sporadic association of two rare diseases rather than constituting an etiologic relationship.

SUDDEN CARDIAC DEATH AND RISK STRATIFICATION

SD may occur in HCM at a wide range of ages, but most commonly during adolescence and young adulthood (usually 12 to 35 years of age) and rarely before 10 years (2–4,57,103,109,111–115) (Fig. 54.8). Indeed, HCM is the most common cause of SD in the young. Although most patients die while sedentary or during normal or modest physical exertion, an important proportion die suddenly during or just after vigorous activity. HCM is also the most common cause of sudden cardiac death in young competitive athletes (2,3,111,116) (Fig. 54.8). This latter observation is the basis for the standard recommendation

FIGURE 54.8. Clinical profile of SD. Top: SD is most common in children and young adults before about 25 years of age, while heart failure and stroke generally occur later in life. (Reproduced from Maron BJ, Olivetto I, Spirito P, et al. Epidemiology of hypertrophic cardiomyopathy-related death. Revisited in a large non-referral-based patient population. *Circulation* 2000;102:858–864, with permission of AHA.) Bottom: HCM is the single most common cause of SD in young competitive athletes in United States. ARVC, arrhythmogenic right ventricular cardiomyopathy; AS, aortic valve stenosis; CAD, coronary artery disease; CHD, congenital heart disease; CM, cardiomyopathy; LAD, left anterior descending; MVP, mitral valve prolapse; WPW, Wolff-Parkinson-White. †Regarded as possible (but not definitive) evidence for HCM at autopsy with mildly increased LV wall thicknesses (18 ± 4 mm) and heart weight (447 ± 76 g). ‡Includes most commonly Kawasaki disease, sickle cell trait, and sarcoidosis. (Reproduced from Maron BJ, Doerer JJ, Haas TS, et al. Sudden deaths in young competitive athletes: analysis of 1866 deaths in the United States, 1980–2006. *Circulation* 2009;119:1085–1092, with permission of AHA.)

to disqualify young patients with HCM from intense competitive sports to reduce their risk for SD under the guidelines of the 36th Bethesda Conference (117).

At present, the greatest risk for SD in children with HCM appears to be associated with one or more of the following clinical risk markers (Fig. 54.9) (118): (a) prior cardiac arrest or sustained ventricular tachycardia (VT) for secondary prevention. For primary prevention: (b) family history of one or more premature HCM-related deaths, particularly if sudden and multiple; (c) unexplained syncope; and (d) massive degrees of LVH (maximum wall thickness ≥ 30 mm, a cutoff independent of age or body size) (Fig. 54.9) and most relevant to young patients. Other risk factors, more applicable to adults with HCM, are multiple, repetitive (or prolonged) nonsustained VT on serial Holter monitoring and hypotensive or attenuated blood pressure response to exercise.

Of note, although the presence of a subaortic gradient (≥ 30 mm Hg at rest) is a strong determinant of progressive heart failure and cardiovascular death (Fig. 54.5) (59), it is a much weaker marker specifically for sudden cardiac death, and consequently obstruction has insufficient power to be regarded as a sole or primary factor to justify primary prevention intervention with an ICD (57). However, due to the substantial genetic heterogeneity in HCM, it is now evident that the prediction of clinical course and SD risk based on knowledge of the disease-causing mutation is unreliable for the management of individual patients (80,81).

Also, the relationship between SD risk and intramuscular course of a segment of the proximal left anterior descending coronary artery (i.e., myocardial bridging; tunneled coronary arteries) in children is not established (119). Electrophysiologic testing with programmed ventricular stimulation has been abandoned as a workable strategy to risk stratify young HCM patients (2,3).

MANAGEMENT

Medical

Response of heart failure symptoms to medical treatment is highly variable, and therapy must often be empirically tailored to the individual requirements of patients (2–5). Figure 54.10 presents a current management algorithm. Since the mid-1960s, various β -adrenergic receptor blocking drugs have been used extensively to relieve and control heart failure symptoms in HCM patients with either the obstructive or nonobstructive forms (2). Long-acting preparations of propranolol, atenolol, metoprolol, or nadolol are now most commonly used. β -blockers may improve symptoms by slowing heart rate and reducing force of LV contraction, thus augmenting ventricular filling and relaxation and decreasing myocardial oxygen consumption. In addition, β -blockers inhibit sympathetic stimulation of the heart and may reduce the outflow gradient under conditions of exercise and augmented sympathetic stimulation.

Most experience with verapamil has been in adult HCM patients (daily dose ≤ 480 mg; 5 mg/kg/day) (120), although some children have also achieved symptomatic benefit from this drug (73,121). Short- and long-term studies have reported oral verapamil to improve cardiac symptoms and exercise capacity, largely in nonobstructive patients, due to a beneficial effect on LV relaxation and filling (72,73). Patients with elevated pulmonary venous pressures, particularly when associated with marked outflow obstruction, may be at increased risk for pulmonary edema or SD while taking verapamil. When patients fail to experience symptom control from β -blockers and verapamil (administered separately), empiric trials with

FIGURE 54.9. SD risk stratification. **Top:** Risk pyramid currently used to identify the most likely high-risk candidates for prevention of SD with ICDs. Depending on the age of the patient, certain markers of risk may be less relevant, for example, NSVT less than age 18 years. BP, blood pressure; LVH, left ventricular hypertrophy; NSVT, nonsustained ventricular tachycardia. **Bottom:** Relation between magnitude of LVH (maximum [max] wall thickness by echocardiography) and SD risk in an unselected HCM cohort. Mild hypertrophy conveys generally lower risk and extreme hypertrophy (wall thickness ≥ 30 mm) the highest risk. CAD, coronary artery disease. (Reproduced from Spirito P, Bellone P, Harris KM, et al. Magnitude of left ventricular hypertrophy predicts the risk of sudden death in hypertrophic cardiomyopathy. *N Engl J Med* 2000;342:1778–1785, with permission of Massachusetts Medical Society.) *Sustained ventricular tachyarrhythmias have been reported in a significant minority of patients short term following the alcohol septal ablation procedure (118).

disopyramide in combination with a β -blocker (122) have been reported to reduce outflow gradient and symptoms. Data on the use of this drug in HCM have to date been largely limited in adults. Diuretic agents may also be administered judiciously, either alone or in conjunction with either β -blockers or verapamil, to reduce pulmonary congestion and improve symptoms. These beneficial actions likely result from a reduction in LV filling pressures.

Patients with HCM may manifest evidence of heart failure in either of two clinical profiles, which largely require different therapeutic strategies (2–5). The usual circumstance occurs in children or adults who experience exertional dyspnea indicative of elevated pulmonary venous pressures, associated with intact or hyperdynamic systolic function. Medical treatment is generally with the aforementioned β -blockers or calcium antagonist drugs, although either medication can be administered first. There is no evidence that taking β -blockers and verapamil together is more advantageous than either drug alone. Furthermore, this combination may lower heart rate and/or blood pressure excessively.

Alternatively, about 3% of HCM patients will manifest the end stage of HCM with systolic dysfunction (ejection fraction < 50%) in which progressive heart failure is often associated with LV remodeling, including wall thinning, and cavity

dilation (56). The therapeutic approach to these patients is similar to that of congestive heart failure in other cardiac diseases, including administration of β -blockers, angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, and diuretics, as well as selectively digoxin, spironolactone, and warfarin.

Bacterial endocarditis appears to be virtually confined to patients with the obstructive form of HCM, with a prevalence of <1% (123). Vegetations most commonly involve the anterior mitral leaflet or septal endocardium at the site of mitral valve–septal contact and less commonly the aortic valve. Therefore, this investigator believes that children with obstructive HCM should receive standard antibiotic prophylaxis prior to dental procedures, despite the recent revised AHA recommendations (124).

Prevention of Sudden Death

In selected patients with evidence of high risk for SD, treatment for the prevention of SD with an ICD is recommended as the only treatment known to extend life in HCM (57). The strategy of long-term prophylactic treatment with amiodarone (125) is obsolete and has been abandoned, and is particularly

FIGURE 54.10. Management strategies for patient subgroups within the broad HCM clinical spectrum. Notably, atrial fibrillation (AF) is distinctly uncommon in the pediatric age group. *Generally no specific treatment or intervention indicated. AF, atrial fibrillation; DDD, dual chamber; ICD, implanted cardioverter-defibrillator; RF, radiofrequency; SD, sudden death.

unrealistic for children given the likelihood of side effects over the long period of risk, as well as the lack of data substantiating the effectiveness of amiodarone in protecting young HCM patients against SD.

The ICD is proven to be effective in high-risk HCM patients by reliably sensing ventricular tachycardia/fibrillation (VT/VF) and restoring sinus rhythm by delivering appropriate defibrillation shocks or antitachycardia pacing (Fig. 54.11) (57,126). The ICD may be lifesaving in young patients, both in the context of secondary prevention after a cardiac arrest (11% per year) or for primary (prophylactic) prevention owing to high-risk status based on the presence of one or more risk factors (4% per year) (57) (Fig. 54.11). Appropriate intervention rates for primary prevention are even higher in young patients, that is, 7%/year when implanted ≤ 20 years of age and 11% per year when implanted ≤ 15 years old, consistent with the known age predilection for HCM-related SD.

Of the single risk factors that triggered the ICD option, unexplained syncope was most commonly associated with appropriate ICD interventions (massive LV hypertrophy in children). Notably, long time periods may elapse between the decision to implant an ICD and when the device is required to issue an appropriate defibrillation shock to terminate VT/VF (Fig. 54.11). The ICD has altered the natural history of HCM for many young patients, and in fact, is the only therapeutic intervention that prolongs life in this disease.

While this consideration for prophylactic ICDs is particularly relevant to young patients who may anticipate extended periods of risk over many decades, the strategy of implanting

young patients with lifelong devices (and perhaps the inevitable possibility of device complications) requires some adjustment in management philosophy within the practicing pediatric cardiology community. Device complications are an important consideration but, nevertheless, the risk for SD in HCM has a predilection for patients in the pediatric age group (particularly adolescents) (2,3,57,126,127). Therefore, to ultimately impede occurrence of SD due to HCM, more of the availability of a definitive intervention such as the ICD probably will be necessary.

Surgical

Based on substantial data accumulated over >40 years, operation for HCM (surgical septal myectomy) is the primary treatment for most patients with severe drug-refractory symptoms resulting in functional disability and associated with mechanical obstruction to LV outflow under basal conditions or with physiologic exercise (gradient ≥ 50 mm Hg) (2–5,128–132). The traditional operative procedure has been the transaortic septal myectomy (Morrow procedure) in which a portion of muscle is resected from the basal septum (usually about 2 to 5 g). At some centers, the myectomy is extended much more distally in the septum (extended myectomy) (129). Results achieved at several institutions with this operation over the past 45 years have been excellent, with the vast majority of patients afforded substantial symptomatic and hemodynamic benefit (2–5,128–132). Operative mortality has steadily

decreased and is now <1% at the most experienced centers. A Mayo Clinic operative series of children with HCM reported zero operative mortality over a 20-year period (131).

More than 90% of patients who undergo myectomy experience abolition or substantial reduction in the outflow gradient under basal conditions (owing to reduction of SAM), but without important compromise in global LV function.

FIGURE 54.11. Prevention of SD. **Top:** Primary prevention. Intracardiac electrogram obtained at 1:20 AM with patient asleep, 5 years after implant. Patient received prophylactic ICD based on family history of SD and extreme ventricular septal thickness. **A:** Ventricular tachycardia (VT) begins abruptly, apparently unprovoked, at 200 beats/minute. **B:** Defibrillator senses VT and charges. **C:** VT deteriorates into VF. **D:** Defibrillator issues 20-J shock (arrow) immediately restoring sinus rhythm. A virtually identical sequence occurred 9 years later, also during sleep; Patient is now 53 years old and asymptomatic. (Reproduced from Maron BJ, Shen WK, Link MS, et al. Efficacy of implantable cardioverter-defibrillators for the prevention of sudden death in patients with hypertrophic cardiomyopathy. *N Engl J Med* 2000;342:365–373, with permission of Massachusetts Medical Society.) **Center:** Flow diagram summarizing ICD-related outcome in 506 high-risk HCM patients from international, multicenter ICD registry (57,126). **Bottom:** ICD intervention rates in patients implanted prophylactically for only one risk factor. ICD, implanted cardioverter-defibrillator; LVH, left ventricular hypertrophy; NSVT, nonsustained ventricular tachycardia.

Long-term follow-up studies from surgical centers have demonstrated that basal outflow obstruction does not recur and heart failure is largely reversed by surgical septal myectomy, with symptoms relieved long term in about 90% of patients (132). Of particular note, recent data from the Mayo Clinic myectomy cohort show that operated patients achieve the same longevity as the general population and demonstrate significantly better survival than nonoperated patients with outflow obstruction (129).

Occasionally, patients develop outflow obstruction from a mechanism other than SAM. For example, anomalous papillary muscle insertion directly into the anterior mitral leaflet (without the interposition of chordae tendinae) produces muscular midventricular obstruction (133,134). This congenital anomaly of the mitral apparatus should be considered prior to intervention since targeted surgical strategy requires distally extended myectomy to relieve obstruction (134).

The technique of alcohol septal ablation has been introduced to reduce outflow gradient in selected symptomatic adult HCM patients as an alternative to surgery (128,135). This method involves introduction of about 2 ml of 95% alcohol into the first major septal perforator to produce a transmural myocardial infarction. This procedure should not be performed (or even considered) in young HCM patients, given their long period of potential longevity and the distinct possibility that the healed scar may enhance the pre-existent arrhythmogenic LV substrate and ultimately increase the risk of SD (128).

ETIOLOGY AND PATHOGENESIS

Cardiac dilation and decreased systolic function, the uniform diagnostic features of dilated cardiomyopathy (DCM), fail to reflect the many causes of DCM (Table 55.1). Infectious, metabolic, ischemic, toxic, and hereditary factors have been implicated in the disease pathogenesis (1–5). DCM, with a prevalence of 36.5 per 100,000 population (1), is thus a final common pathway for diverse disease processes that lead to heart failure. When an infant or child presents with echocardiographically confirmed DCM, knowledge of the broad differential diagnosis and additional testing may uncover a reversible cause for myopathic heart failure and/or aid in establishing prognosis (6,7). However, the primary cause of DCM is unknown in 66% of children (7) and 50% of adults (8). The preclinical cascade of molecular and cellular events leading to heart failure thus remains poorly understood. Most patients with idiopathic DCM have clinically silent disease in childhood, developing symptoms only in middle age (mean age at diagnosis 45 ± 17 years) (9). The delayed onset of clinically apparent disease suggests a subtle congenital defect in myocardial function inciting a gradual degenerative process that progresses over several decades.

Sensitive preclinical markers of DCM unfortunately are lacking, and family history may be the only clue prompting echocardiographic screening and presymptomatic diagnosis in hereditary forms of DCM. Despite an insidious onset, advanced myocardial disease with substantial maladaptive ventricular remodeling often is present in both adults and children with symptomatic DCM. As a result, DCM is the indication for cardiac transplantation in 31% of infants and 64% of older children (10). Late diagnosis is confounded further by limited evidence-based guidelines for the treatment of cardiomyopathic heart failure in children (11). Indeed, conventional medical therapies with established efficacy in adults appear to have a limited impact on pediatric outcomes (12,13). Consequently, only 46% of children with DCM are alive and free from cardiac transplantation at 10 years of follow-up (7). The prognosis in individual patients, nevertheless, often is unpredictable ranging from intractable heart failure to occasional spontaneous recovery (1,14). Improved treatment and prevention of DCM will require identification of preclinical markers, new insights into disease mechanisms and risk classification, and optimal therapies that specifically alter pathologic molecular and cellular processes prior to the development of end-stage myocardial disease.

Cardiac Dilation

Cardiac performance is determined by preload, afterload, contractility, and heart rate. In the normal heart, dilation, like hypertrophy, may represent an appropriate response to

(patho)physiologic demands. According to the Frank-Starling Law, increased preload results in enhanced cardiac output. For example, increased left ventricular end-diastolic volume may be an adaptation to inadequate systemic oxygen delivery (chronic anemia) or contractile dysfunction (acute hypoxic-ischemic insult). In idiopathic DCM, by contrast, dilation initially or eventually becomes maladaptive. The cardiothoracic ratio on chest radiography is predictive of mortality in patients with DCM (1). Moreover, clinical studies of familial DCM indicate that left ventricular dilation is present in 9% to 20% of asymptomatic relatives and serves as a marker for later progression to DCM (9,15,16). It is unknown whether dilation initially is an adaptive response to myocellular dysfunction or a primary, pathologic process of ventricular remodeling. In either case, unless wall thickness increases, dilation leads to increased wall stress (Laplace law) and mismatch of myocardial oxygen supply and demand. In fact, decreased posterior wall thickness in DCM is associated with a worse prognosis (1).

Myocellular Hypertrophy and Death

In acquired forms of heart failure due to ischemia or increased afterload, cardiac hypertrophy is an adaptive response that preserves myocardial performance. Although myocardial mass is increased in DCM because of a severalfold increase in interstitial collagen content (17), left ventricular posterior wall thickness is normal or decreased (2). On microscopic examination, compensatory hypertrophy of viable myocytes is present in human DCM and in animal models of DCM (18,19). However, cumulative loss of myofibrils and cardiac myocytes, lacking sufficient capacity to regenerate (20), occurs concomitantly. Consequently, ongoing myocyte death coupled with progressive chamber dilation contributes to lack of compensatory increase in wall thickness. Myocyte loss in chronic DCM occurs by two general processes—apoptosis, programmed cellular self-destruction (21), and subclinical necrosis, detected by release of cardiac enzymes into the blood stream (22). Quantitative morphometric studies of pathologic heart specimens confirm that cardiac myocyte death is a major pathologic process in DCM (23) and correlates with worse prognosis (2).

Extracellular Matrix Remodeling

Cardiac myocytes play an indispensable role in the heart, yet they constitute only one-third of total myocardial cells (24). Fibroblasts, vascular smooth muscle, and endothelial cells make up the remainder of cells and, unlike cardiac myocytes, retain the capacity to rapidly proliferate. The extracellular matrix is composed of connective tissue proteins such as collagen, fibronectin, and laminin (25). These proteins form a scaffold that maintains cardiac architecture

TABLE 55.1 Causes of Dilated Cardiomyopathy

Acute and chronic myocarditis
Autoimmune disease
Chronic tachycardia
Drugs—alcohol, sympathomimetics, anthracyclines
End-stage hypertrophic cardiomyopathy
Endocrine—growth hormone deficiency, thyroid disease, hypocalcemia, diabetes mellitus, pheochromocytoma
Hereditary—autosomal dominant, autosomal recessive, X-linked, mitochondrial
Inborn errors of metabolism
Infiltrative—glycogen storage disorders, hemochromatosis, amyloidosis
Ischemic—atherosclerosis, Kawasaki disease, anomalous origin of left coronary artery
Muscular dystrophies
Nutritional deficiency—selenium, carnitine, thiamine
Peripartum
Structural heart disease
Systemic hypertension
Toxins—cobalt, lead

and myocyte alignment, and transmits mechanical force generated by cardiac myocytes (17). Ventricular remodeling is a pathologic process of the failing heart, whereby cardiac fibroblasts proliferate, mechanically stable cross-linked collagen is degraded by metalloproteinases, and an excess of poorly cross-linked collagen is deposited into the interstitium (17). In DCM, this remodeling process contributes to both increased myocardial mass, owing to interstitial fibrosis, and ventricular dilation and wall thinning, owing to slippage of aligned myocytes (24). Contemporary medications to treat heart failure, such as angiotensin-converting enzyme (ACE) inhibitors and beta-receptor blockers, may exert their beneficial effects by retarding or reversing maladaptive ventricular remodeling (26).

Familial Dilated Cardiomyopathy

Prior to 1992, the importance of hereditary factors in the pathogenesis of idiopathic DCM was not fully recognized. A focused family history identified a hereditary form of DCM in only 6% to 8% of cases (9). Moreover, when familial and nonfamilial cases of idiopathic DCM were compared, no differences in baseline clinical, serologic, histopathologic characteristics, or long-term outcome were observed to help distinguish familial cases (9,27,28). The concept of DCM as a genetic disorder received major impetus from a 1992 study in which first-degree relatives of index patients were screened by echocardiography (9). DCM was identified in presymptomatic members of several families, accounting for a 20% frequency of familial disease in this patient cohort. A similarly designed study identified familial disease in 25% of cases (29). In both studies, the average age at diagnosis in probands and their relatives was in the fourth to fifth decade, yet children in their first decade of life also were diagnosed with either symptomatic or clinically silent DCM. In children presenting with idiopathic

DCM, recent epidemiologic studies show an 8% to 19% frequency of familial disease despite lack of systematically applied family screening (4,5). If less stringent criteria, such as isolated left ventricular enlargement or sudden unexplained death, are used to diagnosis DCM in relatives, the frequency of familial DCM may be as high as 35% to 48% (15,30).

Familial DCM most commonly is inherited as an autosomal dominant trait, conferring a 50% risk of DCM for children of an individual with DCM (31). Less commonly, DCM is an X-linked disorder in males who have inherited a mutation from their mothers who exhibit only mild or no cardiac disease (32,33). Autosomal recessive and maternally inherited forms of DCM, as in disorders of cardiac energy metabolism (34), are relatively rare and frequently are associated with neuromuscular disease or metabolic derangements. Only one instance of autosomal recessive inheritance of nonsyndromic DCM has been reported (35).

Penetrance and Expression

Traits such as subtle skeletal myopathy, cardiac conduction system disease, and atrial arrhythmia segregate with DCM in certain families with autosomal dominant or X-linked disease (30,36–38). These phenotypic subtypes may suggest specific gene defects and predict progression of DCM (39). Most reports of familial DCM as an isolated disorder or as part of a syndrome, however, have shown age-dependent penetrance and variable expression of disease among members of the same family. Some carriers of a gene mutation may not have DCM or may have an intermediate cardiomyopathy phenotype, such as isolated left ventricular enlargement or conduction system disease. Consequently, interpretation of a normal or nondiagnostic screening echocardiogram and electrocardiogram in a child or adolescent at risk for familial DCM should take into account disease penetrance as low as 5% to 20% in this age group (40). Conversely, when a child presents in congestive heart failure, familial DCM may not be suspected because of variable expression, for example, a parent with a milder form of DCM who is asymptomatic (41,42). Collectively, family-based studies of DCM provide the rationale for clinical screening by echocardiography and electrocardiography in first-degree relatives, regardless of family history or age of the index case (9,15,16,31). Early diagnosis and treatment of asymptomatic DCM may prevent or attenuate heart failure (26). Moreover, in individuals with a recognized genetic predisposition to DCM, close surveillance and modification of acquired traditional risk factors can be implemented to reduce the overall risk burden for heart failure.

Dilated Cardiomyopathy Genes

Dramatic technologic advances in DNA and genomic analysis have evolved over the last half-century, beginning with Watson and Crick's discovery of the double helical structure of DNA and culminating in the decoding of the entire human genome through the Human Genome Project. These advances, together with the emerging recognition of DCM as a familial disorder (9), have culminated in discovery of mutations in 37 genes that cause or confer susceptibility to DCM (43–45) (Table 55.2). While a majority have been identified by hypothesis-based candidate gene approaches, unanticipated DCM genes have been revealed by genomic mapping in multigenerational families (32,37,38,48,50,57,66) or microarray-based “molecular karyotyping” (67). In a less restrictive classification scheme, which includes DCM associated with primary skeletal myopathies, multisystem

Genes for which DCM is only associated with primary skeletal myopathies, multisystem syndromes, or metabolic disorders are excluded.

*Charcot-Marie-Tooth disease, Emery-Dreifuss muscular dystrophy, familial partial lipodystrophy, Hutchinson-Gilford progeria syndrome, limb girdle muscular dystrophy, LVNC.

*Brugada syndrome, heart block, long QT syndrome 3, sick sinus syndrome, ventricular fibrillation, atrial fibrillation.

HCM, hypertrophic cardiomyopathy; CK, creatine kinase; LVNC, left ventricular noncompaction; ATP, adenosine triphosphate; RCM, restrictive cardiomyopathy.

syndromes, or metabolic disorders, an even larger number of genes have been identified (44). Mutations in known genes are estimated to account for only a third of cases (43), however, prompting continued research efforts to discover novel DCM genes. No common gene (genetic heterogeneity) or mutation (allelic heterogeneity) for DCM has emerged. However, targeted genetic testing of *LMNA* (encoding lamin A/C, a nuclear membrane protein) and *SCN5A* (encoding the cardiac sodium channel) may be justified in the subset of patients with DCM associated with atrial arrhythmia and conduction system disease (37,38). In addition, early-onset, clinically aggressive DCM has been reproducibly associated (albeit not invariably) with mutations in *TNNT2* (encoding cardiac troponin T) and *RBM20* (encoding RNA binding motif protein 20), and recurring mutations/mutation hot-spots have been identified in these genes (43,66). To address the challenge of marked genetic and allelic heterogeneity in DCM, chip-based resequencing arrays have been developed to facilitate efficient clinical genetic testing of many of the established DCM genes (76).

Knowledge of the molecular underpinnings of DCM continues to evolve with the identification of mutant genes that serve diverse functions within the heart, implicating perturbation of distinct biologic pathways in myopathic heart failure (see Table 55.2; Fig. 55.1). In a broad classification scheme, eight types of heritable myocellular defects have been linked to DCM: (a) disruption of cytoskeletal structure/integrity ($n = 13$); (b) altered contractile force transmission or generation ($n = 8$); (c) defective nuclear structure ($n = 3$); (d) altered gene transcription or translation ($n = 3$); (e) dysregulation of ion flux ($n = 3$); (f) disruption of extracellular matrix structure/integrity ($n = 2$); (g) impaired protein-protein interactions ($n = 4$); and (h) deficit in stress adaptation ($n = 1$). The emerging technology of next generation sequencing, enabling comprehensive mutation scanning of all genes, provides an unprecedented opportunity to complement traditional disease gene discovery strategies (77). Ongoing discovery of novel DCM genes, together with biochemical, cellular, and animal studies of DCM-associated mutant proteins, will continue to advance our understanding of the pathobiology of myopathic heart failure.

Figure 55.1. Defects in proteins governing diverse myocellular processes lead to cardiac remodeling and the phenotype of dilated cardiomyopathy. (Modified from Olson TM. Monogenic dilated cardiomyopathy. In: Walsh RA, ed. *Molecular Mechanisms of Cardiac Hypertrophy and Failure*. London: Taylor & Francis, 2005:525–540.)

Clinical Heterogeneity

Clinical and genetic overlap of familial DCM with other cardiac and noncardiac disorders is an established paradigm (Fig. 55.2). For example, mutations in the same gene can lead to muscular dystrophies with variable cardiac involvement or to DCM with subclinical skeletal muscle involvement, evident only by elevated serum muscle creatine kinase (32,33). Similarly, heritable defects in certain contractile and other proteins can cause dilated, hypertrophic, restrictive, or left ventricular noncompaction cardiomyopathy. The divergence of cardiac remodeling pathways into either dilated congestive heart

failure or pathologic cardiac hypertrophy can be attributable partially to mutation-specific effects. For instance, mapping of *cardiac actin* mutations in an atomic model of the actin-myosin complex indicated that hypertrophic cardiomyopathy-associated mutations were in myosin-binding domains critical for contractile force generation (41,78). In contrast, DCM-associated mutations were in anchoring domains that transmit contractile force from the thin filament to other myocellular proteins. The modifying effects of other genes also are important in cardiac remodeling pathways. This is exemplified by an animal model of genetic cardiomyopathy in which development of either dilated or hypertrophic cardiomyopathy

Figure 55.2. Heritable defects in dystrophin cause muscular dystrophy and/or dilated cardiomyopathy. Similarly, amino acid substitutions in cardiac actin cause either dilated cardiomyopathy (purple residues) or hypertrophic cardiomyopathy (green residues). (From Olson TM. Monogenic dilated cardiomyopathy. In: Walsh RA, ed. *Molecular Mechanisms of Cardiac Hypertrophy and Failure*. London: Taylor & Francis, 2005:525–540, with permission.)

depends on genetic background (79). This concept was established further by identification of similar or identical cardiac sodium channel mutations in humans that cause either isolated rhythm disorders or a syndrome of DCM, conduction disease, and atrial fibrillation (38).

CLINICAL FEATURES AND TREATMENT

History

Patients with DCM usually develop symptoms correlating with the degree of myocardial dysfunction. The onset of symptoms often is gradual unless it is due to acute viral myocarditis. Shortness of breath and exercise intolerance are the most common symptoms in the older child and are related to low cardiac output and pulmonary venous congestion. In severe cases, fulminant pulmonary edema may occur. In younger children, especially infants, the symptoms are often vague. They present with tachypnea, dyspnea, irritability, and poor feeding. Additional symptoms related to recent viral infections, signs of rheumatic fever, and Kawasaki disease may coexist in patients who develop a cardiomyopathy secondary to these inflammatory diseases. A history of dry skin and peripheral edema may indicate hypothyroidism.

A careful family history is critical to identify hereditary forms of DCM. Also, one must identify previous exposure to cardiac toxins, especially previous chemotherapeutic agents. Trypanosomiasis and Lyme disease should be suspected if recent travel into endemic areas has occurred. A history of cardiac surgical procedures and tachyarrhythmias should be determined.

Physical Examination

A child who has heart failure may be anxious, diaphoretic, tachycardic, and tachypneic. Grunting may result from efforts to minimize alveolar collapse secondary to pulmonary edema. Often, accessory muscles are recruited for increased respiratory effort. The older child often may have orthopnea. Wheezing is common. Of note, these patients will rarely respond to beta-receptor agonist aerosol treatments. Indeed, use of these agents may be detrimental owing to their possible arrhythmogenic potential.

The patient may be febrile because of an acute infectious illness that may be exacerbating symptoms that otherwise would be subtle. The patient's blood pressure can be low because of inadequate cardiac output. Invariably, the heart rate is elevated. If the tachycardia exceeds the maximum heart rate for age, supraventricular tachycardia or ventricular tachycardia should be considered. The oxygen saturation level often is within normal limits except in severe cases when pulmonary edema has affected normal gas exchange.

Palpation of the precordium usually demonstrates an apical impulse displaced downward and laterally. A right ventricular lift may be present as a result of elevated pulmonary artery pressure. The first heart sound often is normal, whereas the pulmonic component of the second heart sound may be increased. An S3–S4 gallop rhythm is often audible. However, the absence of a gallop rhythm may occur in a patient who is *in extremis* owing to severe congestive heart failure. If the heart sounds are distant, it is imperative to exclude pericardial effusion. Jugular venous distention may be present but is difficult to appreciate in young infants.

A murmur of mitral regurgitation is common. This murmur is coincident with the first heart sound and best heard at the apex and the left lower sternal border. It can be accentuated by having the patient lean forward while in the sitting position or lie in the left lateral position. With improved ventricular function in response to therapy, the murmur may become more prominent, and S3 and S4 may be heard.

A distended abdomen is common. The liver span is increased with descent of the liver edge. Occasionally there may be ascites. Pretibial edema can be present in older patients. The extremities may be cool and poorly perfused because of vasoconstriction. Capillary refill time can be increased.

Electrocardiogram

There usually is sinus tachycardia. The presence of incessant supraventricular or ventricular tachycardia should be treated aggressively because these rhythms are poorly tolerated in patients with DCM. Indeed, these tachyarrhythmias may be the cause of the cardiomyopathy. Left ventricular hypertrophy often is present and manifest by increased left precordial voltages (Fig. 55.3). Nonspecific ST-segment and T-wave abnormalities often are present. The presence of deep Q waves in leads I and aVL should suggest anomalous origin of the left coronary artery from the pulmonary artery.

Figure 55.3. (A,B) correspond to limb leads and precordial leads, respectively. Twelve-lead electrocardiogram of a 14-year-old boy with severe dilated cardiomyopathy. Note the voltages are at one-quarter standard and the recording speed is 50 mm/s. There is severe left ventricular hypertrophy. There are also T-wave and ST-segment changes. An ectopic atrial beat is seen in leads V1, V2, and V3R.

Figure 55.4. Posteroanterior (A) and lateral (B) chest roentgenograms of the same patient shown in Figure 55.3, demonstrating marked cardiomegaly, elevated left mainstem bronchus from left atrial enlargement, and pulmonary congestion.

Thoracic Roentgenography

The cardiothymic silhouette is enlarged mainly because of left atrial and ventricular dilation (Fig. 55.4). Left atrial enlargement may cause elevation of the left main stem bronchus. Pulmonary venous congestion and pulmonary edema often are evident. The pattern of the increased pulmonary vascular markings is reticular. Pleural effusion may be present, demonstrated by loss of the sharp posterior and lateral pleural angles. Lateral decubitus films better define the location and extent of any fluid collection.

Doppler Echocardiography

Echocardiography is an excellent noninvasive method for detecting DCM. The cardiac chambers, especially the left atrium and ventricle, are enlarged (Fig. 55.5). End-diastolic and end-systolic volumes are increased when indexed to body surface area. Systolic function is decreased and can be assessed by shortening fraction and ejection fraction. Segmental dyskinesia may suggest an ischemic cause for the cardiomyopathy. During diastole, nonapposition of the mitral valve to the interventricular septum can be measured as E-point septal separation. This displacement is most notable on M-mode echocardiography and reflects left ventricular enlargement. In severe cases, spontaneous echogenic signals result from slowly moving red blood cells and may predict an increased risk of spontaneous thrombosis. Occasionally, fibroelastosis may be demonstrated by an echo-bright appearance to the endocardium. Care should be taken to

document the origin of the coronary arteries, especially the left. The presence of diastolic flow in the main pulmonary artery toward the transducer may indicate the presence of anomalous pulmonary artery origin of the left coronary artery. Additional coronary artery abnormalities such as aneurysms or ectasia also should be identified. With DCM, the vena cavae and hepatic veins may be dilated. Pericardial and pleural effusion may be evident.

Mitral regurgitation is well demonstrated by color-flow Doppler imaging (Fig. 55.6). If tricuspid regurgitation is present, Doppler interrogation can estimate the right ventricular systolic pressure, and in the absence of right ventricular outflow obstruction, pulmonary arterial systolic pressure. Doppler interrogation of the ascending aorta may demonstrate decreased forward flow, and diastolic flow reversal may occur in the descending aorta.

Cardiac Catheterization

Indications for cardiac catheterization include documentation of coronary artery anatomy and endomyocardial biopsy. The presence of left ventricular thrombus is a relative contraindication for cardiac catheterization. Meticulous monitoring should be performed at all times. Catheter manipulation can result in arrhythmias, and the laboratory should be equipped to handle any emergencies.

A carefully planned hemodynamic study should include pressure measurements in the aorta, left ventricle, pulmonary capillary wedge position, and pulmonary artery. Cardiac output calculated by the Fick method or thermodilution

Figure 55.5. A: Two-dimensional echocardiographic findings of a patient with dilated cardiomyopathy. Note the severely dilated left atrium and ventricle. B: M-mode findings of another child with congestive cardiomyopathy. Note the large chamber dimensions and the depressed systolic wall motion. LA, left atrium; LV, left ventricle.

often will demonstrate a low cardiac index. Angiography should include an ascending aortic injection. Selective coronary angiography sometimes is needed to clearly define these vessels.

Endomyocardial biopsy may be helpful in determining the cause of the myopathy. Because of frequent nonuniformity of myocardial involvement, there can be false-negative results. Standard techniques using either the femoral or internal jugular vein approaches may be chosen depending on the experience of the operator. How the specimen is going to be used should be well defined prior to the biopsy so that unnecessary sampling can be avoided. After the biopsy is performed, a pericardial effusion from perforation of the thinned myocardium can be excluded by echocardiography.

Figure 55.6. Two-dimensional echocardiographic image with color-flow Doppler demonstrating severe mitral regurgitation seen in a case of severe dilated cardiomyopathy. (From Armstrong WF, Ryan T. *Feigenbaum's Echocardiography*, 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:519, with permission.)

Treatment

Please refer to other chapters on Chronic Congestive Heart Failure (Chapter 73) and Cardiac Intensive Care (Chapter 20) for comprehensive discussions of management of chronic heart failure and acute decompensated heart failure in children. This section provides a framework for treatment options, with specific issues unique to DCM, where necessary.

The clinical picture of a patient with symptomatic DCM usually consists of low cardiac output, fluid retention, and increased peripheral vasoconstriction owing to neurohumoral activation to maintain adequate perfusion pressure. The goals of medical therapy, therefore, are to address each of these issues. Additionally, if a metabolic abnormality is present, appropriate treatment should be started without delay. Recent practice guidelines for the management of heart failure in children have been reported. These recommendations largely represent expert consensus opinion in the absence of randomized clinical trials (80). Nonetheless, this document is the most contemporary consensus resource providing guidelines for care of heart failure in children.

Combined Inotropic and Vasodilator Support

The phosphodiesterase inhibitors milrinone and amrinone increase stroke work and cardiac output. Both systemic and pulmonary vascular resistances are decreased, and these drugs evoke unique lusitropic properties affecting relaxation and ventricular compliance. Because of untoward side effects, amrinone is no longer used. Milrinone, a bipyridine compound and derivative of amrinone, is the primary agent of choice. This drug is thought to promote increase in intracellular calcium concentration by inhibition of phosphodiesterase III. In studies done in adults, potential side effects included thrombocytopenia, hypotension, and arrhythmias. In children, the efficacy of milrinone is supported by the prevention of low cardiac output syndrome after biventricular repair (PRIMACORP multicenter trial). However, there have been no longitudinal studies in pediatric patients with cardiomyopathy and decompensated heart failure. In the PRIMACORP trial, milrinone did not have the same incidence of side effects that were reported in adults (81,82). Many clinicians use

milrinone for decompensated heart failure, often in combination with catecholamines such as dobutamine or dopamine. Synergistically, these medications may augment cardiac output via different mechanisms and may prove beneficial in lowering pulmonary vascular resistance. The half-life of milrinone varies depending on the age of the patient but generally is between 1 and 4 hours. The dose should be adjusted if there is renal impairment.

Levosimendan is a calcium-sensitizing agent that has been evaluated in adults with acute decompensated heart failure and in patients with chronic heart failure (83–86). This agent binds to troponin-C in cardiac myocytes and improves cardiac contractility. It also opens adenosine triphosphate (ATP)-sensitive potassium channels causing peripheral arterial and venous dilation. There is no increase in myocardial oxygen consumption or arrhythmias. Although initial experience with levosimendan was encouraging in both adults and children (87), results from a large prospective randomized trial failed to show any benefit of levosimendan over dobutamine in 180-day mortality or any other secondary outcomes (88).

Catecholamines

Sympathomimetic agents, such as dopamine, dobutamine, isoproterenol, and epinephrine, stimulate adrenergic receptors directly and/or indirectly. The average half-life of these medications is 2 to 7 minutes, and steady-state concentrations are reached in 10 to 15 minutes. Many patients are treated with beta-blockers such as carvedilol. One must be careful when administering catecholamines to patients receiving beta-blocking drugs because the alpha-adrenergic effects of the catecholamines may predominate in the presence of beta-blockade. Many clinicians consider phosphodiesterase inhibitors to be the treatment of choice for patients who are taking beta-blocker drugs. Milrinone retains its full hemodynamic effects in the presence of beta-blocker therapy.

Digoxin

Digoxin, a cardiac glycoside, is the primary long-term medication used to improve ventricular contraction. It blocks the $\text{Na}^+\text{-K}^+$ ATPase pump, resulting in increased intracellular calcium concentrations. Its effectiveness as an inotropic agent has been questioned, but it continues to be used widely. An additional potential benefit of digoxin may be its central nervous system effects that lessen sympathetic tone. This may decrease heart rate, allowing more efficient ventricular filling.

Digoxin should be used with caution in acutely ill children. In this group of patients who may have decreased renal function, drug toxicity can occur owing to decreased renal excretion of the medication. Additionally, some clinicians believe that the use of digoxin in patients with an inflamed myocardium may promote ventricular arrhythmias. Careful attention to normalize electrolytes, especially potassium, will help to minimize the potential for digoxin toxicity. There is evidence that lower serum concentrations of digoxin in adults may be safer and possibly more beneficial than higher serum concentrations (89,90). Use of digoxin has been controversial in many clinical situations in pediatric cardiology. Extrapolated from adult trials, digoxin is not recommended for pediatric patients who have asymptomatic left ventricular dysfunction, yet digoxin, in low doses, is recommended for those patients who are symptomatic (80).

Diuretics

Furosemide is the agent of choice in most patients with fluid overload. Its primary mode of action is to block electrolyte reab-

sorption at the loop of Henle. Thus, monitoring the electrolyte status is imperative. Hypokalemia can be avoided by using KCl supplementation or by the addition of spironolactone. Spironolactone, a weak diuretic, can help maintain potassium homeostasis by countering the actions of aldosterone. In adults, spironolactone was shown to improve survival (Randomized Aldactone Evaluation Study). This study was terminated early because patients had improved survival, reduction in hospitalizations, and improved New York Heart Association class (91). A similar survival benefit was found in the study of the newer aldosterone antagonist, eplerenone, in adults with heart failure (92). The potential mechanisms of this benefit are complex, and may be at least partially related to an attenuation of aldosterone-induced myocardial fibrosis or catecholamine release (93).

Other potent diuretics include ethacrynic acid and bumetanide. These drugs also act at the loop of Henle. The effects may be synergistic with other diuretics. As with furosemide, electrolyte imbalance can occur with aggressive diuresis. Excessive diuresis may reduce preload and lead to diminished cardiac output. Thiazides should be considered as additive therapy for those patients who become resistant to loop diuretics, or who require additional diuresis. A recent study failed to show any benefit of continuous infusion of diuretics over high-dose intermittent infusion of diuretics in adults with acute decompensated heart failure (94).

Vasodilator Agents

Nitroprusside and hydralazine effectively dilate peripheral vessels and decrease afterload, increase cardiac output, and decrease filling pressures. The action of both agents is relaxation of smooth muscle cells in the muscular layer of arterioles. Prolonged nitroprusside use can result in cyanide accumulation, a metabolic by-product of the drug. A possible side effect of hydralazine is a lupus-like reaction.

Effective orally administered afterload-reducing agents include ACE inhibitors. Captopril and enalapril are used most commonly in children. Other commonly used agents are monoproil, lisinopril, and quinapril. The choice depends on cost and dosage convenience. The actions of ACE inhibitors include decreased synthesis of angiotensin II, a potent vasoconstrictor, and decreased breakdown of bradykinins, which are potent vasodilators. Additional effects of these medications include sparing urinary potassium loss by inhibiting aldosterone secretion.

The use of ACE inhibitors has gained wide acceptance for treating children with DCM. This has been supported by large multicenter studies in adults that demonstrated improved survival in patients with chronic congestive heart failure treated with enalapril. Angiotensin receptor blockers have been studied in adult patients, but there are no data in pediatric patients with heart failure. Studies in adults have not shown significant differences between ACE inhibitors and angiotensin receptor blockers in either efficacy or safety. Angiotensin receptor blockers do not cause bradykinin accumulation and thus do not cause cough as a side effect as occurs with ACE inhibitors (80). In patients of African ancestry with DCM and heart failure, one may want to consider the use of isosorbide dinitrate and hydralazine (95).

Beta-Blocking Agents

Clinical trials have suggested that carvedilol, a drug that has both beta-receptor-blocking and vasodilating actions, improved the left ventricular performance and clinical status of adult patients with heart failure (96–100).

Both metoprolol and carvedilol use has been reported in children. Many of these early studies showed a beneficial effect in a subset of patients (101–104). However, in the prospective, randomized, multicenter trial of carvedilol in children with heart

failure, carvedilol failed to show a benefit over placebo (added to background therapy) on a composite endpoint of clinical heart failure outcomes in children with symptomatic heart failure (11). In a prespecified analysis, the response to carvedilol may be dependent on ventricular morphology, in that there was a significant difference in the degree of improvement in those whose systemic ventricle was a left ventricle compared with those whose systemic ventricle was a right or single ventricle.

Other Therapeutic Options

Antiplatelet and antithrombotic agents may have a role in the treatment of DCM. The propensity for thrombus formation in patients with large cardiac chambers and blood stasis may prompt the use of antiplatelet or antithrombotic agents such as aspirin, low molecular weight heparin, or warfarin. Certainly, if thrombi are detected, they should be treated aggressively with heparin and then with warfarin.

Bed rest may be helpful for the acutely ill child. Salt and free water intake may need to be restricted. Careful attention to daily weights is an effective gauge of diuretic therapy and the degree of fluid retention.

If carnitine deficiency is the cause of the cardiomyopathy, carnitine supplementation must be started without delay. Confirmatory diagnostic testing from urine and plasma sampling can still be performed with concurrent treatment of the presumed deficiency.

Antiarrhythmic drugs and/or radiofrequency ablation are used when the diagnosis of tachycardia-induced cardiomyopathy is established. The therapy of choice depends on the cause of the tachyarrhythmia. Many effective antiarrhythmics, such as procainamide, may have negative inotropic effects and should be used with caution in this group of patients. Ultimately, these patients should be considered for ablative therapy as a potential cure.

Cardiac Resynchronization Therapy

Resynchronization therapy in adult patients with a left bundle branch block (QRS duration ≥ 130 ms) and decreased ventricular function (ejection fraction $\leq 35\%$) has proven to be efficacious in improving symptoms and decreasing hospitalization rates (105,106). A few experiences with this therapy in pediatric patients, including those with congenital heart disease, have been published (107–109). Further studies are necessary before the usefulness of this type of treatment for children is known.

ICD Implantation

Implantation of a defibrillator for secondary prevention due to previous arrhythmic event is a fairly well-accepted practice (110). In contrast, primary prevention among children is not well established. Reports of ICD use in children with DCM are extremely limited. Extrapolation of indicators from large multicenter studies with adults should be done with caution as the heterogeneity of etiologies is quite different between the two age groups.

The obvious indication for ICD implantation is to prevent sudden cardiac death. A large single center study has reported only a 1% incidence of sudden death (111,112). This would suggest primary prevention in this cohort is usually not indicated. To further the difficulty in offering guidelines for primary prevention, the single case of sudden cardiac death did not have a history of sustained arrhythmias.

Cardiac Transplantation

For a more complete discussion of heart transplantation, see Chapter 65. Transplantation should be considered if short-term survival is unlikely or for severe symptoms unresponsive

to conventional therapy. Griffin et al. (113) identified age at presentation, presence of arrhythmias, and heart size as useful determinants of timing for cardiac transplantation. Lewis and Chabot (114) suggested that left ventricular end-diastolic pressure >25 mm Hg is a predictor of poor outcome and therefore an indication for earlier transplantation. In a multivariate analysis, investigators concluded that although pediatric patients with DCM may have one of many outcomes, recovery is the most frequent. The greatest risk of death or transplantation was associated with age younger than 1 year or older than 12 years, and female sex. With transplantation, 1- and 5-year actuarial survival for pediatric patients with DCM was 90% and 83%, respectively (115).

Natural History of Dilated Cardiomyopathy

The natural history of DCM in children is difficult to predict owing to the heterogeneous diseases that can result in cardiomyopathy. If the cause for the cardiomyopathy is identified and is treatable, such as carnitine deficiency, one should expect a high survival rate. Children with idiopathic DCM constitute the cohort of most studies that attempt to identify predictors of poor outcome. The actuarial survival rate in this group of patients is 63% to 90% at 1 year and 20% to 80% at 5 years (7,113–116). The cause of death usually involves ventricular arrhythmias and progressive intractable ventricular failure or, more rarely, complications of heart transplantation. Among the survivors, about half demonstrate an improvement in cardiac function. Taliercio et al. (119) reported that a history of viral symptoms within 3 months of presentation was associated with improved survival.

The presence of arrhythmias is not uniformly predictive of poor outcome. Indeed, patients may succumb at the time of their initial documented arrhythmia. However, patients with treatable arrhythmias, supraventricular or ventricular, had a higher survival rate when the arrhythmia was adequately controlled (114,118).

Intracardiac thrombi were identified in 16% to 23% of patients by thorough 2-D echocardiograms (119). In a study of autopsy specimens, 43% had thrombi (117). Although thrombus is not a predictor of survival, it does point to the importance of anticoagulation therapy and the potential morbidity in this group of patients.

Other suggested predictors of outcome include cardiothoracic ratio on chest roentgenograms, electrocardiogram abnormalities such as ST-T wave changes, left ventricular hypertrophy, left atrial enlargement, right atrial enlargement, and right ventricular hypertrophy. Unfortunately, none of these factors is a dependable predictor of survival.

Jeffrey A. Towbin ■ Angela Lorts ■ John Lynn Jefferies

Myocarditis is an inflammatory disease of the myocardium with necrosis and/or degeneration of adjacent myocytes not typical of the ischemic damage associated with coronary artery disease (1). This definition does not take into account the underlying causative mechanism of disease.

ETIOLOGY

Many cases of myocarditis remain unrecognized because they may have a nonspecific or benign presentation leaving the true incidence of myocarditis unknown. However, in those children presenting with dilated cardiomyopathy (DCM), myocarditis (46%) is the most frequent *known* cause for this newly diagnosed myocardial disease (2). Cases that are definitively diagnosed as myocarditis in developed countries are most commonly a result of a viral infection diagnosed by the molecular biologic amplification method called polymerase chain reaction (PCR) from an endomyocardial biopsy (EMB) (3–6). The true incidence of viral-induced myocardial inflammation is difficult to predict since children with new-onset DCM are infrequently biopsied due to the small but measurable risk of myocardial perforation or the development of untoward hemodynamic or arrhythmic events during the catheterization and biopsy. However, using data from both pediatric and adult centers, it has been shown that the most common virus detected, in those patients who have had a biopsy, has shifted with each decade. In the 1970s and 1980s, coxsackievirus was the most common viral etiology in both adult and pediatric patients, but in the 1990s and early 2000s, the most common viral causes included adenovirus (especially serotypes 2 and 5) (7,8) and enterovirus (coxsackieviruses A and B, echovirus, and poliovirus), particularly coxsackievirus B (CVB) (9,10) (Table 56.1). Most recently, parvovirus B19 (PVB19) has become the most commonly identified virus in patients with myocarditis (11–17). Many reports have shown a strong association between inflammation, coronary artery inflammation and insufficiency, and resulting systolic dysfunction with PVB19 infection, but interestingly, approximately 50% of adult patients with isolated diastolic dysfunction were also found to be PCR positive for a viral genome, most commonly PVB19 (17).

Although there is an era effect, many other viral causes of myocarditis (18) have been described, including influenza A (19), influenza H1N1 (20,21), cytomegalovirus (CMV) (22), herpes simplex type 2 (HSV) (23), hepatitis C virus (24,25), rubella (26), varicella (27), mumps (28), Epstein-Barr virus (EBV) (29), human immunodeficiency virus (HIV) (30), human herpesvirus (HHV6) (31), respiratory syncytial virus (32), among others. Other nonviral causes include other infectious agents such as rickettsiae, bacteria, protozoa, and other parasites, fungi, and yeasts (Table 56.2) (33–44); various drugs, including antimicrobial medications (45); hypersensitivity,

autoimmune, or collagen-vascular diseases (46–48) such as systemic lupus erythematosus, mixed connective tissue disease, rheumatic fever, rheumatoid arthritis, and scleroderma; toxic reactions to infectious agents (49) (e.g., mumps or diphtheria); or other disorders such as Kawasaki disease and sarcoidosis (Table 56.3) (50,51).

EPIDEMIOLOGY

Myocarditis is an underdiagnosed entity, but estimates of the incidence can be made via review of autopsy results. In the large multicenter Myocarditis Treatment trial, there was a reported incidence of myocarditis in 9% of adult patients (52). A review of all autopsies in children ($n = 1,516$) at a single center over a 10-year period demonstrated that only 1.8% of postmortem exams were consistent with myocarditis. Of the positive cases, 57% had presented with sudden cardiac death (6). Viral myocarditis is a major cause of unexpected death in persons <40 years of age and may progress to DCM, which is a major health concern worldwide (53,54).

Usually sporadic, viral myocarditis can also occur as an epidemic, correlating with viral outbreaks (55). In children and adults, outbreaks usually occur in a seasonal distribution.

In pediatrics, the prevalence of virus-associated myocarditis is highest in the neonatal period, and the most common etiology in this age group was previously CVB, but PVB19 has been important this past decade as well. In the case of CVB, the neonatal infection can be secondary to intrauterine exposure or postnatal spread of coxsackievirus via the fecal/oral or airborne route. Other important viral causes, such as PVB19, adenovirus, and influenza A, are transmitted through the air.

CLINICAL MANIFESTATIONS

Presentation depends on the age of the child (4,18,56). Nonspecific flu-like illness or episodes of gastroenteritis may precede symptoms of congestive heart failure.

Newborns and Infants

Newborns or infants present with poor appetite, vomiting, fever, irritability or listlessness, pallor, and diaphoresis. Sudden death may occur in this subgroup of children (57). On physical examination, pallor, in addition to classic signs of congestive heart failure, such as hepatomegaly, tachypnea, tachycardia, and occasionally a gallop, is commonly noted. It is important to keep in mind that the younger the child, the more likely it is that intrauterine myocarditis is now expressed as a chronic disease (18,49).

TABLE 56.1 Viral Causes of Myocarditis

Enterovirus	Varicella
Coxsackie A	Mumps
Coxsackie B	Measles
Echovirus	Rabies
Poliovirus	Hepatitis B, C
Adenovirus	Rubella
Parvovirus B19	Rubeola
Cytomegalovirus	Respiratory syncytial virus
Herpesvirus	Human immunodeficiency virus
Influenza A and H1N1	Epstein-Barr virus
Human herpesvirus 6	

Children and Adolescents

Older children and adolescents commonly have a recent history of viral disease 10 to 14 days prior to presentation. Initial symptoms include lethargy, low-grade fever, and pallor; the child usually has decreased appetite and associated vomiting with complaints of episodic abdominal pain. Diaphoresis, palpitations, rashes, exercise intolerance, and general malaise are common signs and symptoms. Later in the course of illness, respiratory symptoms become predominant; syncope or sudden death may occur owing to cardiac collapse. Physical examination findings are consistent with congestive heart failure (8), as

described above. Unlike in newborns, jugular venous distention and pulmonary rales may be observed, and resting tachycardia may be prominent. Occasional ectopy and arrhythmias including atrial fibrillation, supraventricular tachycardia, ventricular tachycardia, and atrioventricular block may occur (56) (Fig. 56.1).

DIAGNOSTIC TESTS

The diagnosis of myocarditis is often difficult to establish but should be suspected in any infant or child who presents with unexplained congestive heart failure or ventricular tachycardia. Each patient must be approached individually recognizing the availability of modalities at the managing institution with the diagnostic evaluation including the following tests.

Chest Radiography

Chest radiography is routinely performed in the evaluation of patients with clinical suspicion of myocarditis. Cardiomegaly is often present with well-described prominent vascular markings of pulmonary edema consistent with left-sided heart failure (Fig. 56.2). There may also be evidence of right ventricular dilation with loss of the retrosternal space on a lateral view if there is biventricular involvement or severe left ventricular disease. Patients with chronic myocarditis may have evidence of left atrial dilation that can result in widening of the carinal angle which is typically <75 degrees. However, a normal radiograph may be seen if the patient presents early in the course.

Electrocardiography

Sinus tachycardia with or without low-voltage QRS complexes and/or inverted T waves is classically described (Fig. 56.3A).

A pattern of myocardial injury or infarction may be seen with changes in ST segments (Fig. 56.3B). These changes may be diffuse or in a defined coronary distribution pattern. With sufficient time and myocardial damage, Q waves may also be seen and are commonly wide and notched. Pericarditis may also accompany the clinical picture with resultant diffuse ST segment elevation. Ventricular arrhythmias including ventricular tachycardia (Fig. 56.3C) and fibrillation, supraventricular tachycardias and atrial fibrillation, or conduction system disease including atrioventricular block (Fig. 56.3D) may occur in some patients and may even be the presenting complaint (58).

Echocardiography

Echocardiography is widely used in the assessment of suspected myocarditis because it is readily available at most institutions. Assessment of chamber size, ventricular thickness, and systolic function has been classically pursued as part of the evaluation as well as evaluation for pericardial effusion (PE). This includes described views with the use of Z-scores based on normal calculations for body surface area. In addition, assessment for segmental wall motion abnormalities is advocated as there may be regional dysfunction in the setting of a normal shortening fraction (SF) and/or ejection fraction (EF). Newer echocardiographic modalities have greatly enhanced the ability to assess diastolic function and should be pursued when possible. A dilated and dysfunctional left ventricle consistent with DCM is often seen on two-dimensional (Fig. 56.4A,B) and M-mode echocardiography (Fig. 56.4C) (59). Segmental wall motion abnormalities are relatively common, but global hypokinesis is predominant. PE frequently occurs. Doppler and color Doppler commonly demonstrate mitral regurgitation (Fig. 56.4A). Dilation of other chambers also may be seen. Newer strategies that assess regional myocardial deformation such as strain and strain rate imaging may offer opportunities to detect myocardial inflammation prior to overt changes in regional or global systolic function (60).

Serologic Testing

Serologic markers are increasingly used to identify ongoing myocardial damage and may offer insight into future prognosis. However, there are no current serologic biomarkers that clearly differentiate myocarditis from other causes of acute myocardial dysfunction such as ischemia. Traditional markers of myocardial cell lysis such as creatine kinase (CK), creatine kinase myocardial band (CKMB), and troponin may be elevated in acute myocarditis and are readily available at the majority of hospitals. The identification of elevated troponin I levels may assist in the identification of pediatric patients with myocarditis but may not be as helpful in predicting outcomes as in the adult with myocardial infarction. (61,62) In actuality, troponin measurements may only be elevated in 35% to 45% of biopsy-proven myocarditis cases. (63) There are increasing reports describing the utility of B-type natriuretic peptide (BNP) in children. Mlczech et al. (64) recently reported serial measurement of NT-pro BNP in children with acute myocarditis and found them to be elevated at time of presentation and that they decreased over the following year with appropriate medical therapy. In addition, nontraditional cardiac biomarkers to assess end-organ function may be of benefit to assist in evaluation for perfusion as well as aiding in the decision to pursue mechanical support (65).

Chest radiograph in a child with acute myocarditis. **Left:** Initial radiograph demonstrating cardiomegaly and increased pulmonary vascular markings consistent with pulmonary edema. **Right:** Radiograph obtained 6 months after initial presentation demonstrates normalization of heart size and lung markings.

Magnetic Resonance Imaging

Advanced imaging techniques have greatly enhanced the opportunities to characterize myocardial inflammation in patients with myocarditis as well as predict all-cause and cardiac mortality. Cardiovascular magnetic resonance (CMR) imaging offers a noninvasive strategy that reports reproducible volumetric and functional data as well as localizing areas of myocardial inflammation and edema. Specific techniques for myocardial characterization have been developed including T2-weighted imaging to localize myocardial edema and T1-weighted contrast enhanced fast spin echo images for hyperemic responses. Furthermore, with the use of gadolinium, late gadolinium enhancement (LGE) can be obtained on technically feasible patients, which will localize areas of irreversible myocardial injury (necrosis and fibrosis) (66). A recent report described 203 consecutive adult patients with biopsy-proven myocarditis who also underwent CMR on presentation as well as during clinical follow-up. The presence of LGE resulted in hazard ratios of 8.4 and 12.8 for all-cause mortality and cardiac mortality, respectively. This was a more robust predictor than the typical echocardiographic markers typically assessed including left ventricular EF and LV end-diastolic volume. Furthermore, no subject without presence of LGE was found to have sudden cardiac death (67). CMR offers a unique modality to follow patients with myocarditis longitudinally assessing for reversible/irreversible myocardial injury, myocardial viability, favorable remodeling, and scar burden (68). All of these findings may have impact on clinical decision making including response to therapy and need for advanced interventions such as implantable cardioverter defibrillators as well as need for cardiac transplantation.

Endomyocardial Biopsy

The gold standard for identification of the underlying cause of acute and chronic myocarditis remains the analyses performed on tissue obtained by EMB. These tests include routine histologic examination as well as targeted immunohistochemical analysis. In addition, we perform viral PCR analysis on all EMB samples, given the inherent limitations of the existing Dallas criteria used for diagnosis (69). Cardiac catheterization typically demonstrates low cardiac output and elevated ventricular end-diastolic pressures in patients with significant myocardial involvement. EMB (Fig. 56.5) from

the right ventricle is evaluated for inflammation (Fig. 56.6). The inflammatory infiltrate is usually patchy and scattered in the ventricular myocardium. A mononuclear cell infiltrate is diagnostic of myocarditis, although this does not delineate cause. EMB is diagnostically sensitive in 3% to 63% of cases (70–73). Because of the reported insensitivity of biopsy, Chow et al. (72) and Hauck et al. (73) reported that to identify 80% of cases, 17 or more specimens must be obtained. Because there is risk associated with EMB, particularly in young children or those with thinning of the ventricular wall and/or active inflammation, many centers have abandoned this procedure. However, in experienced centers, the risk associated with EMB is quite low in children of all age groups (74). It should be noted that foci of inflammation may be seen in all forms of cardiomyopathy, irrespective of etiology, due to the disruption of cardiomyocytes as part of the pathophysiology and cellular biology of the disease. These are not cases of myocarditis in the usual sense.

The Dallas Criteria

The Dallas Criteria define myocarditis as “a process characterized by an inflammatory infiltrate of the myocardium with necrosis and/or degeneration of adjacent myocytes not typical of ischemic damage” owing to coronary artery or other disease (75). At the time of initial EMB, a specimen may be classified as active myocarditis, borderline myocarditis, or no myocarditis, depending on whether an inflammatory infiltrate occurs in association with myocyte degeneration or necrosis (active), too sparse an infiltrate, or no myocyte degeneration (borderline) (75). Repeat EMB may be appropriate in cases where strong suspicion of myocarditis exists clinically; on repeat EMB, histology may be classified as ongoing myocarditis, resolving myocarditis, or resolved myocarditis. However, increasing evidence has led to more extensive studies on EMB samples including histopathology, immunohistochemistry, viral PCR, and cardiac antibody testing to better make the diagnosis of myocarditis.

Viral Studies

A positive viral culture from the myocardium has been considered the diagnostic standard in the past. Viral culture of peripheral specimens, such as blood, stool, or urine, is commonly

Figure 56.3. Electrocardiogram in a case of myocarditis. A: Sinus tachycardia and low-voltage QRS complexes with inverted T waves. Color Doppler interrogation provides evidence of mitral regurgitation. **B:** Parasternal short-axis view demonstrating LV dilation and normal papillary muscles (P). **C:** M mode demonstrating systolic dysfunction with flattened interventricular septal (IVS) motion, fair LV posterior wall (LVPW) excursion, LV dilation with increased LV end-diastolic dimension (D), and reduced systolic function (S) and PE. Ao, aorta; LA, left atrium; MR, mitral regurgitation.

Figure 56.5. Endomyocardial biopsy technique. The biptome is advanced via the superior vena cava into the right atrium, across the tricuspid valve into the right ventricle, and finally situated against the interventricular septum, where the biopsy is performed. The biptome also can be advanced via the inferior vena cava with similar results. (Reprinted from Towbin JA. Molecular genetic aspects of cardiomyopathy. *Biochem Med Metab Biol* 1993;49:285–320, with permission from Elsevier.)

performed but is unreliable in identifying the causative infection. A fourfold increase in antibody titer correlates with infection (76). However, these studies are nonspecific because prior infection with the causative virus is commonplace. PCR

Figure 56.6. Endomyocardial biopsy histology demonstrates lymphocytic infiltrates, myocardial edema, and necrosis.

(5) amplifies viral sequences from cardiac tissue samples, is extremely sensitive, and is typically specific.

Molecular Diagnostics

First reported in 1986, in situ hybridization was performed on myocardial tissue using probes for coxsackievirus (65,66) (Fig. 56.7). This technique is difficult to use in a hospital setting and, for this reason, lost favor and has never gained widespread use. The PCR amplification process, which identifies specific portions of a viral genome, is quite sensitive and specific (5,7) (Fig. 56.8). Around 20% to 50% of cases were initially reported to identify enterovirus PCR-positive results although no other viral genome was analyzed in these early cases (77–79). PCR also has been used to screen for other viral genomes within cardiac tissue specimens. We showed that adenovirus (Fig. 56.9) is identified as commonly as enterovirus in heart tissue specimens of patients with myocarditis or DCM in the 1990s and through 2003 (Table 56.4) (18). Additional viral genomes identified using PCR include CMV, parvovirus, respiratory syncytial virus, EBV, HSV, and influenza A virus. (18,80,81) Mumps virus (Fig. 56.10) is responsible for endocardial fibroelastosis (EFE), a previously important cause of heart failure in children that has decreased significantly over the past three decades (49). Since 2000, other viruses have been increasingly reported as causative

Figure 56.7. In situ hybridization using coxsackievirus B3 probe. A: Note the brown-stained coxsackievirus in the infected myocytes. B: Negative control. Detection of coxsackie-B virus specific RNA sequences in myocardial biopsy samples from patients with myocarditis and dilated cardiomyopathy. *The Lancet* 1986;327:1120–1123, with permission from Elsevier.)

Figure 56.8. PCR for enterovirus. Note the 151-bp band on this agarose gel in the enterovirus-positive (+) control and patient (Jx) lanes. The negative control is devoid of any band, excluding contamination. Another patient (Th) is negative for enterovirus.

of myocarditis including PVB19 (82). HHV6 is becoming increasingly recognized as a cause of viral myocarditis worldwide (31).

PCR analysis may identify viral genome in peripheral blood of patients with myocarditis in about one-third of cases, but the viral genome has been shown to be able to be identified in tracheal aspirates of intubated children with myocarditis, potentially reducing the need for EMB (83).

DIFFERENTIAL DIAGNOSIS

Any cause of acute circulatory failure may mimic myocarditis. Table 56.5 lists the differential diagnosis of congestive heart failure based on the age range of the child.

PATHOPHYSIOLOGY

Viral infection triggers interstitial inflammation and myocardial injury, resulting in cardiac enlargement and an increase in ventricular end-diastolic volume (84) (Fig. 56.11). Normally, this increase in volume results in an increased force of contraction, improved EF, and improved cardiac output as described by the Starling mechanism. In myocarditis, the myocardium is unable to respond to these stimuli, resulting in a reduction in stroke volume. Figure 56.11 identifies the following domino effect of the various changes that occur and result in the pathophysiologic response in patients with myocarditis.

1. Interactions with the sympathetic nervous system may preserve vital systemic blood flow via vasoconstriction, but this will increase afterload on the failing myocardium. This sympathetic nervous system input results in a preserved blood pressure (initially), tachycardia, and diaphoresis.
2. Congestive heart failure ensues with disease progression. The progressive increase in ventricular end-diastolic volume and pressure results in increased left atrial pressure, which is transmitted into the pulmonary venous system. This causes increasing hydrostatic forces, which overcome the colloid osmotic pressure that normally prevents transudation of fluid across the capillary membranes. This results in pulmonary edema.
3. Concomitantly, all cardiac chambers dilate, particularly the left ventricle. This dilation, in addition to causing poor ventricular function, creates worsening pulmonary edema and worsening cardiac function. The ventricular dilation also results in stretching of the mitral annulus and resultant mitral regurgitation, further increasing left atrial volume and pressure.
4. During the healing stages of myocarditis, fibroblasts replace normal myofibers and result in scar formation. Reduced elasticity and ventricular performance can result in persistent heart failure. In addition, ventricular arrhythmias commonly accompany fibrosis.

PATHOLOGY

Gross and Microscopic Findings

Pathologic findings are nonspecific, with similar gross and microscopic changes noted irrespective of the causative agent (4). The heart weight is increased, and all four chambers are affected. The muscle is flabby and pale, with petechial hemorrhages often seen on the epicardial surfaces. A PE also may be seen relating to the often combined finding of pericarditis (in other words, myopericarditis). The ventricular wall is frequently thin, although hypertrophy may be found as well. The valves and endocardium are usually not involved.

In cases of chronic myocarditis, the valves may be glistering white, consistent with EFE, suggesting the result of long-standing inflammation in patients or even an in utero viral myocarditis in newborns with findings of heart failure (85). In North America, newborn EFE has become quite rare. Among children with myocarditis compared with those who had EFE in a prior era, those with myocarditis typically had symptoms for <2 weeks, whereas those with EFE had symptoms for >4 months. Mumps and CVB3 have been identified in the myocardium of infants with EFE, consistent with this being a viral-induced disorder in the past, and its disappearance consistent with the disappearance of these inciting viruses (49).

Mural thrombi can occur in the left ventricle, and small emboli are often found in the coronary and cerebral vessels (86). Coronary emboli, although rare, may produce areas of ischemia or injury with resultant production of the cardiac arrhythmias that sometimes occur during the acute disease. Coronary insufficiency appears to be a common occurrence in children with PVB19 myocarditis as PVB19 infects the endothelium, including coronary endothelium, and not myocytes.

An interstitial collection of mononuclear cells, including lymphocytes, plasma cells, and eosinophils (Fig. 56.6) is typical of early myocarditis (9). Polymorphonuclear cells are rare, as are viral particles. Extensive necrosis of the myocardium, with loss of cross-striation in the muscle fibers and edema, is seen

Figure 56.9. PCR for adenovirus. **A:** Control analysis. The *left panel* shows an agarose gel with a 308-bp PCR-positive band in the adenovirus-positive control only. In the adenovirus-positive lane and in control patients 1 and 2, K-ras, a constitutive product of all cells that is used to show extracted nucleic acid, is positive in each. The *right panel* identifies a Southern blot of the left panel with a radioactive probe specific for adenovirus. **B:** The *left panel* shows a PCR-positive 308-bp band in the two right ventricular endomyocardial biopsy (RVEMB) samples and negative in the lane of blood. The *right panel* again shows adenoviral specificity. **C:** DNA sequencing of RVEMB1 is consistent with type 2 adenovirus in the patient, which is compared with the sequence of the type 5 positive control. A, adenine; C, cytosine; G, guanosine; T, thymidine.

in severe infections, especially with coxsackievirus. Perivascular accumulation of lymphocytes and plasma cells has been described with CVB myocarditis but is usually a minor finding. This is a much more prominent finding in disease caused by rickettsiae, varicella, trypanosomes, or other parasites, and in reactions to sulfonamides (87). In cases of adenoviral myocarditis, mild to moderate inflammation with moderate to severe fibrosis was common, while coronary insufficiency is common with PVB19.

Diphtheria myocarditis is frequently complicated by arrhythmias and complete atrioventricular block (88). Diphtheria exotoxin attaches to conduction tissue and interferes with protein synthesis by inhibiting a translocating enzyme in the delivery of amino acids (88). Triglyceride accumulates, producing fatty changes of the myofibers.

Bacterial myocarditis produces microabscesses and patchy focal suppurative changes. A combined perimyocarditis is also frequently encountered. Parasitic myocarditis caused by trichinella has a focal infiltrate with lymphocytes and eosinophils, but larvae are usually not identified (37).

A severe myocarditis caused by *Trypanosoma cruzi* results in Chagas disease, which can have both acute and chronic cardiac sequelae (89,90). Rare in North America, Chagas disease is endemic in South America, affecting ≤50% of the population. Microscopic examination shows the organism as well as neutrophils, lymphocytes, macrophages, and eosinophils.

Sudden death in infancy may result from myocardial inflammation. James described a resorptive, degenerative process in the His bundle and left margin of the atrioventricular node with the absence of inflammatory cells in cases of infants who died in northern Ireland (91).

Giant cell myocarditis (GCM) is a rare, virulent form of myocarditis and is thought to have an autoimmune basis that is histologically defined by the presence of multinucleated giant cells, a lymphocytic inflammatory infiltrate, and myocyte necrosis. It usually occurs in children and young adults and reportedly has a high risk of death unless cardiac transplantation is performed. GCM has been considered to have an underlying autoimmune basis due to its association with other autoimmune disorders, thymoma, and drug hypersensitivity, and is associated with immune-mediated disease in other organs. GCM occurs with tuberculosis, syphilis, rheumatoid arthritis, rheumatic heart disease, sarcoidosis, and fungal or parasitic infections (51,92–94). Giant cells also occur in idiopathic (Fiedler) myocarditis. There are two types of giant cells: cells originating from the myocardium and cells derived from interstitial histiocytes.

Immunology

The immunopathogenesis of CVB and encephalomyocarditis has been studied in mice. CMV, HIV, and adenovirus models also have been described (95–100).

TABLE 56.4 Myocarditis Etiologic Agents in Children by PCR Analysis

Diagnosis	No. of Samples	No. of PCR + Samples	No. of PCR Amplimer
Myocarditis	624	239 (38%)	Adenovirus 142 (23%) Enterovirus 85 (14%) CMV 18 (3%) Parvovirus 6 (<1%) Influenza A 5 (<1%) HSV 5 (<1%) EBV 3 (<1%) RSV 1 (<1%)
DCM	149	30 (20%)	Adenovirus 18 (12%) Enterovirus 12 (8%)
Controls	215	3 (1.4%)	Enterovirus 1 (<1%) CMV 2 (<1%)

CMV, cytomegalovirus; DCM, dilated cardiomyopathy; EBV, Epstein-Barr virus; HSV, herpes simplex virus; PCR, polymerase chain reaction; RSV, respiratory syncytial virus.

Twenty-four to seventy-two hours after infection with CVB, a viremia exists, with maximum growth in the tissues at 72 to 96 hours (9). Shortly thereafter, virus titers decline; essentially no organisms can be found by 7 to 10 days after inoculation. As virus titers decline, antibody concentrations increase, implying that antibody has an active role in viral clearance. Macrophages appear 5 to 10 days after infection in the CVB model of myocarditis (9).

Risk factors for severe myocarditis include age, mouse strain, viral variant, exercise, and sex (9). Pathogenetic mechanisms

include direct viral myofiber destruction and T-lymphocyte cytotoxicity (97–99,101). Animals with absent or blocked T-cell function have less myocardial injury.

The natural killer (NK) cell is important in the pathogenesis of myocarditis. Animals that are depleted of their NK cells prior to infection with coxsackievirus develop a more severe myocarditis (84). NK cells are activated by interferon, which is an indirect modulator of myocardial injury. Murine skin fibroblasts serve as target cells for CVB-sensitized cytotoxic T cells. The NK cells specifically limit the nonenveloped virus infection by killing the virally infected cells. Male mice are less efficient in activating NK cells. Presumably, the more efficiently viral clearance occurs, the less virally induced neoantigen production occurs, reducing recognition by cytotoxic T lymphocytes.

T cells can affect injury by accumulation of activated macrophages, production of antibody and antibody-dependent cell-mediated cytotoxicity, direct lysis by antibody and complement, and direct action of cytotoxic T cells (102). In the BALB/c mouse, the greatest susceptibility was between 16 and 18 weeks, with males having a more rapid and severe course of myocarditis than that seen in females. Estradiol decreased severity, and testosterone increased the cytolytic activity in males. Either a preferential stimulation of T helper cells or an inadequate stimulation of T-cytolytic/suppressor cells could explain why antibody responses to various antigens may frequently be enhanced and cellular immune responses depressed in females.

Host genetic composition affects not only the severity of disease but also pathogenic mechanisms (100,101,103,104). The BALB/c mouse developed myocarditis in response to cytolytic T cells. Two distinct cytolytic T-cell populations are formed in the BALB/c mouse: one recognizing virus-infected cells and producing direct myocytolysis, and another that destroys uninfected myocytes and is believed to be an autoreactive lymphocyte. Complement depletion increased the amount of inflammation in this species, and no reactive immunoglobulin G antibody was found in the myocytes. In the DBA/2 mouse, it was the T helper cells that indirectly mediated the course of disease, and complement depletion reduced inflammation in this species. Cytolytic T cells were found to be produced but apparently were not pathogenic; immunoglobulin G antibody was found in the myocytes.

In humans, antibody-mediated cytotoxicity was found among 30% of patients with suspected myocarditis, as well as in 18 of 19 patients with proven viral infections owing to CVB,

influenza A, or mumps virus (95). A muscle-specific antimyolemmal antibody was found in these patients and correlated with the degree of in vitro–induced cytolysis of rat cardiocytes. Bowles et al. (105,106) used complementary DNA (to CVB2 RNA) cloning techniques and developed a CVB-specific complementary DNA hybridization probe that detected virus nucleic acid sequences in patients diagnosed as having active or healed myocarditis or DCM. As controls, they used patients with unrelated disorders and found no virus-specific sequences in those patients (105). This suggested that viral particles persist in patients with congestive cardiomyopathy or healing myocarditis, even though viral culture is almost always negative. The findings imply a continual viral replication in cells, which may conceal the antigenicity by an immunologic process that prevents correct posttranslational processing of capsid proteins. Hori et al. (107) found adult patients with myocarditis to have been exposed to a greater number of CVB1 to CVB6, as

demonstrated by the number of positive and negative responses to neutralizing antibodies of those viruses. They believed that immunization against several types of CVB was essential in the development of myocarditis. Although they postulated this cross-immunization theory, a few cases of myocarditis in their patients involved exposure to only one type of CVB, shedding doubt on the validity of their theories.

Defective cell-mediated immunity occurs in patients with myocarditis and DCM when compared with healthy controls. Pathogenesis of adenoviral myocarditis differs from CVB (108,109). The inflammatory infiltrate is substantially less in adenoviral infection (110). The number of CD2, CD3, and CD45RO lymphocytes seen in the adenovirus-infected patients was reduced compared with those patients who had myocarditis not owing to adenovirus (110). The adenoviruses have a number of strategies for modulating the immune response, which could impact the number of activated lymphocytes in

Figure 56.11. Pathophysiology of myocarditis. AV, atrioventricular; CHF, congestive heart failure; LVEDP, left ventricular end-diastolic pressure; LVEDV, left ventricular end-diastolic velocity; VT, ventricular tachycardia.

the adenovirus-infected myocardium (99). Several adenovirus-encoded proteins can interact with host immune components, including proteins encoded by the E3 region, which can protect cells from tumor necrosis factor (TNF)-mediated lysis, as well as downregulation of major histocompatibility complex class I antigen expression. The E1A proteins are capable of promoting the induction of apoptosis (111) and inhibiting interleukin-6 (IL-6) expression, as well as interfering with IL-6 signal transduction pathways. These functions of E1A may be pertinent to the development of the myocardial pathology seen in DCM. First, IL-6 promotes lymphocyte activation, which is reduced in adenovirus-infected patients. In addition, it has been shown that apoptotic cells occur in the myocardium of patients with DCM. Taken together, these events are likely to result in DCM.

Autoimmunity

Persistent viral infection of the myocardium is linked to the induction of autoantibodies against the adenine nucleotide translocator (ANT) and myosin (112,113). ANT shuttles energy from the mitochondria to the cells, whereas myosin is a contractile protein (Fig. 56.12).

Anti-ANT antibodies correlate with cardiac dysfunction (112). An increase in the ANT1 isoform was detected in patients together with a concomitant decrease in ANT2. Furthermore, in patients with enterovirus infection, this was more pronounced than in patients in whom no enterovirus was detected. In animal models of CVB3 infection, nucleotide transport is inhibited. ANT1 transgenic mutant mice have a cardiomyopathic phenotype, supporting the concept that it is important in cardiac function (114).

Novel autoantigens also have been identified in patients with myocarditis (115–117). These include dihydrolipoamide dehydrogenase and sarcomere-specific CK. It is not clear, however, if these autoantigens are important pathogenetically. As yet, autoantibodies associated with persistent adenovirus infection of the myocardium have not been described.

Role of Cytokines in Myocarditis and Dilated Cardiomyopathy

Over the past several years, there has been considerable interest in the role of cytokines in the pathogenesis of myocarditis and DCM (103,118). Recent animal studies suggest that a relationship may

exist between subclinical viral infection and later development of DCM. This process is presumed to occur by an autoimmune-like mechanism triggered by the initial viral insult. Several murine models have been studied that suggest that cytokine-mediated modulation of the immune response to viral infection may lead to induction of chronic autoimmune myocarditis (118–124). Cytokines contribute to regulation of antibody production and maintenance of self-tolerance. Susceptible murine strains, when infected with CVB3, develop myocyte necrosis and an acute inflammatory response. After the initial viral infection, resolution of inflammation eventually occurs. In other strains, however, a second autoimmune phase of myocarditis appears later, with findings of diffuse mononuclear cell infiltrates within the heart. These mononuclear cells are a significant source of the cytokines IL-1 and TNF- α , and they release large amounts of TNF- α and IL-1 β by human monocytes when exposed to CVB3 (119). Both of these cytokines are known to participate in leukocyte activation, which may be beneficial in promoting a specific lymphocyte response to viral infection. However, these cytokines also may promote cardiac fibroblast activity. Therefore, it has been speculated that local secretion of cytokines in the myocardium perpetuates the inflammatory process, which secondarily leads to the fibrosis associated with DCM and resultant deterioration of cardiac function.

IL-1 and TNF- α are potential inhibitors of cardiac myocyte β -adrenergic responsiveness, and further studies have shown IL-1 and TNF- α to be the macrophage factors mediating this effect (118). TNF- α levels are elevated in patients with chronic heart disease, myocarditis, or DCM. TNF- α is able to potentiate the immune response and induce apoptosis in cells, integral to the pathogenesis of myocarditis. Other inflammatory mediators, including IL-1 and granulocyte colony-stimulating factor, are also elevated in myocarditis patients. Inflammatory cytokines may cause a direct negative inotropic response.

The role of cytokine activity relative to the pathogenesis of viral myocarditis or subsequent development of chronic autoimmune myocarditis is under investigation. Mice that are genetically resistant to postinfection autoimmune myocarditis develop severe disease when infected with CVB3 in addition to therapy with lipopolysaccharide, TNF- α , or IL-1 (121). CVB3 infection of cardiac tissue likely promotes local production of cytokines by activated monocytes as a response to viral infection. Anti-TNF- α blocks or reduces the severity of myocarditis. Thus, local TNF- α expression is sufficient to cause cardiac pathology and dysfunction and support its role in human disease.

Figure 56.12. ANT and its role in energy utilization.

IL-2 limits myocardial damage when administered in the acute viremic stage by enhancing NK cell activity (122,123). In contrast, IL-2 exacerbated the course and severity of the disease when given in the subacute, nonviremic stage by increasing the number of infiltrating T cells. IL-12 protects mice from encephalomyocarditis virus-induced myocarditis (124). IL-12 augments cytotoxic activity and induces Th1-specific immune responses.

Cytokines may act through inducible nitric oxide synthase (iNOS) (124). In a cardiac myosin-induced myocarditis model, NOS expression is induced in both macrophages and cardiomyocytes. However, nitric oxide synthesis did not appear to be essential for the development of pathology because myocarditis developed in mice lacking interferon regulatory transcription factor (IRF)-1, a transcription factor that controls iNOS expression. Despite the failure to synthesize NOS in the myocardium, the prevalence and severity of disease in IRF-1-deficient animals were similar to results observed in control animals. In addition, no difference was detected in animals lacking the IRF-2 gene, a negative regulator of IRF-1-induced transcription.

In the rat model, nitric oxide expression is critical to the pathology of autoimmune myocarditis (124). Rats that were treated with aminoguanidine, an inhibitor of iNOS, had only focal mononuclear infiltration and reduced numbers of cardiomyocytes positive for iNOS, by comparison with untreated animals that had considerable inflammatory infiltration and myocyte damage. In addition, serum levels of CK were significantly reduced in the treated animals, indicating reduced muscle damage. In a separate study of autoimmune myocarditis in the rat, IL-2 levels appeared early, whereas IL-3, TNF- α , and iNOS were present later, during the period of peak inflammation. IL-10 was detected only after inflammation began to subside and persisted during recovery. These data support the notion that changes in the Th1 and Th2 responses are important for controlling outcome, as previously suggested for CVB3-induced myocarditis.

It is difficult to extrapolate the information obtained in animal models of myocarditis to human disease. Further studies to clarify the role of cytokines and nitric oxide in the pathogenesis of myocarditis in humans are warranted, as is consideration of the potential efficacy of drugs to inhibit cytokine or iNOS expression. We need to know if virus persistence combined with ongoing IL-6, IL-8, and TNF- α expression, in the absence of IL-10, leads to the progression from myocarditis to DCM.

Role of Cell Adhesion Molecules in Myocarditis and Dilated Cardiomyopathy

Cell adhesion molecules (CAMs) also may play a role in the pathogenesis of myocarditis (108). One molecule that is well

known to play a major role in cell-cell adhesion, particularly leukocyte adherence and transendothelial migration, is intercellular adhesion molecule 1 (ICAM-1). ICAM-1 is a member of the immunoglobulin supergene family of CAMs and is a single-chain glycoprotein of 80 to 115 kDa with an extracellular domain made up of five immunoglobulin-like repeats. ICAM-1 is predominantly expressed on endothelial cells, but also on fibroblasts, epithelial cells, mucosal cells, lymphocytes, monocytes, and cardiac myocytes after inflammatory injury. Expression of ICAM-1 on endothelial cells is upregulated by cytokines such as IL-1 and TNF- α . A well-established binding ligand of ICAM-1 is lymphocyte function-associated antigen 1 (LFA-1), a molecule that is part of the β 2 integrin family and consists of a 180-kDa α subunit (CD11a) and a 95-kDa β subunit (CD18). LFA-1 is expressed on virtually all leukocytes, including monocytes. The adhesive interaction between LFA-1 and ICAM-1 mediates adhesion-dependent helper T cell, cytotoxic T cell, and NK cell functions. Antibody to LFA-1 blocks inflammatory response in animal models of myocarditis.

Apoptosis

Apoptosis, or programmed cell death, has an important role in embryogenesis, tissue homeostasis, and regulation of immunologic responses, among normal physiologic processes, and is associated with the growth and regression of tumors (108). Cells undergoing apoptosis exhibit characteristic morphologic and biochemical features, including chromatin aggregation, nuclear and cytoplasmic aggregation, and formation of apoptotic bodies resulting from the partition of the cytoplasm and nucleus into membrane-bound vesicles. These apoptotic bodies are rapidly phagocytosed by adjacent macrophages or epithelial cells, without resulting in an inflammatory response. Apoptotic cells are detectable by terminal transferase labeling (terminal deoxynucleotide transferase-mediated biotin-deoxyuridine triphosphate nick end labeling [TUNEL]) in myocardial tissue samples from patients with DCM. It has been shown that up to 0.1% of cells stained positive by this technique.

Several viruses have been implicated in the induction of apoptosis, including HIV, EBV, and adenovirus. Apoptotic cells are detected in adenovirus-associated myocarditis and DCM (Fig. 56.13). Within such areas, $\leq 1\%$ of cells may stain positive, including myocytes, infiltrating inflammatory cells, and endothelial cells. In the tissue sections from control patients, either unstained cells or sporadically stained cells (one or two per section) may be detected. These data suggest a relationship between infection of the myocardium by adenovirus and the onset of apoptosis, which could result in pathologic processes

Figure 56.13. A: TUNEL (see text) staining of endomyocardium demonstrates apoptotic bodies (red inclusions). B: Negative control.

Figure 56.14. Illustrated adenovirus structure (top), with electron micrographs below. Note the hexagonal shape and its projections.

associated with myocarditis and DCM. Furthermore, a number of inflammatory cells may be seen to be undergoing apoptosis. Although this could reflect the natural defense mechanism of the host against the virus, it also raises the possibility of virus-induced apoptosis as a mechanism of immune system avoidance. In tumors, infiltrating immune cells are destroyed by the induction of apoptosis through the expression of Fas ligand on the tumor cell that binds Fas on the lymphocyte.

Two of the genes of adenovirus (Fig. 56.14), E1A and E1B, regulate apoptosis via a p53-dependent pathway (109). The expression of E1A in cells results in the induction of apoptosis, but the coexpression of E1B (or the bcl-2 proto-oncogene) suppresses this effect and results in cell transformation. E1B encodes 19- and 55-kDa proteins, either of which can suppress apoptosis. The 55-kDa protein of E1B binds to, and inhibits, p53, but the mechanism of suppression by the 19-kDa protein is unknown.

As previously noted, most models of experimental myocarditis have used CVB3 variants. It has been known for a number of years, however, that different variants induce different pathologic mechanisms and that different strains of mice are affected differently. Infection of BALB/c, MRL^{+/+}, or DBA/2 mice with a cardiotropic variant of CVB3 resulted in similar levels of inflammation, but only in DBA/2 mice was antiheart immunoglobulin G generated (84). Few CD8⁺ T cells infiltrated the myocardium of MRL^{+/+} and DBA/2 mice, but in BALB/c mice, they are the major component of the T-cell response. The detection of apoptotic cells using TUNEL staining revealed no apoptotic cells in DBA/2 myocardium, inflammatory cells undergoing apoptosis in MRL^{+/+} mice, and myocyte and inflammatory cell apoptosis in BALB/c mice (92). In BALB/c mice with myocarditis, there was a decrease in ventricular contractility, indicative of cardiomyopathy, whereas in DBA/2 mice, there was no change in contractility.

LONG-TERM SEQUELAE

Many cases of myocarditis survive the critical phase of illness. It is increasingly recognized that myocardial dysfunction and evidence of heart failure can present at some point during their lifetimes (70,125–127). It remains unclear what the underlying cause of these long-term sequelae could be, but viral persistence and autoimmunity have been widely speculated. Enteroviral protease 2A directly cleaves the cytoskeletal protein dystrophin, resulting in dysfunction of this protein (Fig. 56.15) (128). Because mutations in dystrophin are known to cause an inherited form of DCM (as well as the DCM associated with the neuromuscular diseases, Duchenne muscular dystrophy, and Becker muscular dystrophy), it is likely that this is, to a large extent, responsible for the chronic DCM seen in enteroviral myocarditis (129,130). Other viruses, such as adenoviruses, also have enzymes that cleave membrane structural proteins or result in activation or inactivation of transcription factors, cytokines, or adhesion molecules to cause chronic DCM (131,132). Andreoletti et al. (133) reported presence of enteroviral infection, specifically CVB, in association with the pathogenesis of acute myocardial infarction secondary to a disruption in the dystrophin–glycoprotein complex. Therefore, it appears that a complex interaction between the viral genome and the heart occurs and results in the short- and long-term outcome of affected patients.

As in mice, myocarditis in humans may have a genetic basis (134). Support for this includes the frequent finding of myocardial lymphocytic infiltrate in patients with familial and sporadic DCM, as well as the few reports of families in which two or more individuals have been diagnosed with myocarditis on EMB. The findings of a common receptor for the four most common viral causes of myocarditis (CVB3 and CVB4 and

adenoviruses 2 and 5), the human coxsackievirus, and adenovirus receptor (CAR) (Fig. 56.16) (135,136), which if mutated could result in responsible host differences leading to myocarditis (137,138), support the concept of a genetic link to virally induced inflammatory heart disease. CAR is a tight junction protein of the intercalated disk and has been linked with the innate immune response in CVB myocarditis (139). Recent mouse studies have shown that CAR upregulation results in myocardial inflammation that is histologically similar to that of early viral myocarditis (140). Newer approaches to genetic

study, including genome-wide association studies, may lead to an enhanced understanding of genetic predispositions for acquiring viral myocarditis.

SUPPORT FOR VIRAL CAUSE-AND-EFFECT RELATIONSHIP WITH MYOCARDITIS

Despite the increasingly common association of viral genome within the myocardium in patients with myocarditis, limited definitive data exist that prove that the virus causes ventricular disturbance directly leading to the clinical phenotype. Many physicians and scientists hold onto the concept that myocarditis is a primary inflammatory disorder, but definitive data are limited to support that hypothesis. Further limiting our understanding of myocarditis and the role of viruses is the low percentage of EMBs performed and the even fewer attempts at performing PCR on the myocardium.

An excellent human model exists, however, that we have studied extensively that offers insight into the acute and chronic effects of cardiotropic viruses. Cardiac transplant recipients undergo routine surveillance EMBs for rejection and, in all cases, histopathology is performed. In our institution, all such subjects also undergo myocardial PCR analysis with screening of adenovirus, enterovirus including coxsackievirus, PVB19, CMV, influenza, HCV, and EBV. We have shown that identification of viral genome in these samples correlated with outcome, with a 96% 5-year survival in subjects not having PCR-positive studies any time during the 5-year follow-up, whereas those with a single PCR-positive result (or more) have a 5-year survival of 67% (Fig. 56.17) (141).

Figure 56.16. Illustrated human CAR.

Figure 56.17. Kaplan-Meier survival curve of adenovirus-positive versus adenovirus-negative PCR from endomyocardial biopsies of cardiac transplant recipients (Reprinted from Shirali GS, Ni J, Chinnock RE, et al. Association of viral genome with graft loss in children after cardiac transplantation. *N Engl J Med* 2001;344:1498–1503, with permission from the Massachusetts Medical Society.)

Interestingly, survival does not closely correlate with the level of inflammatory infiltrate seen on histopathology. This appears, at least in part, to do with the specific viruses identified in the myocardium. Adenovirus tends to cause a lower level of inflammatory infiltrate than enteroviruses or PVB19 (141). We have reported that cardiotropic viruses continue to be a significant cause of pediatric heart transplant dysfunction and that this disease is shifting with respect to the viruses involved, specifically an endemic shift to PVB19 in the current era (16). Furthermore, we recently reported that viral endomyocardial infection is an independent predictor of graft loss in pediatric heart transplant patients that appears to be mediated by premature development of transplant coronary artery disease (TCAD) (82). Interestingly, patients who were treated with IVIG and were PCR-positive on EMB had a delayed time in the development of TCAD suggesting a possible treatment strategy. Similar findings have been found in lung transplant recipients (Fig. 56.18) (142).

Adenovirus infection in the lung results in graft failure after lung transplantation. *J Thorac Cardiovasc Surg* 1998;116:617–623, with permission from Elsevier.)

TREATMENT

The care for patients with suspected or proven myocarditis must be individualized given the wide range of presenting symptoms that may vary from being relatively asymptomatic to cardiogenic shock. Continual reassessment of patients with myocarditis is recommended as their clinical picture can change dramatically in a very short period of time. Many patients present with relatively mild disease, with minimal or no respiratory compromise and only mild signs and/or symptoms of congestive heart failure. These patients require close hemodynamic and electrocardiographic monitoring to assess whether the disease will progress to worsening heart failure and the need for more intensive medical care. Murine models of myocarditis suggest that exercise may result in increased viral replication as well as myocardial inflammation and necrosis (143). Thus, it appears prudent to place patients under this restriction at the time of diagnosis. Normal arterial blood oxygen levels should be maintained for any patient with compromised hemodynamics resulting in hypoxemia.

Although no specific therapy aimed at reversing myocardial injury is currently widely recommended, maintenance of cardiac output at levels that supply adequate tissue perfusion and prevent metabolic disturbances and end-organ dysfunction is critical to good outcome.

Medical Management

The appropriate medical management of patients with myocarditis is dependent on their clinical presentation. Patients presenting with mild symptoms of congestive heart failure and preserved cardiac output should be continually evaluated as they may progress to a more decompensated state. Diuretics may be used judiciously to treat symptoms of shortness of breath or peripheral edema. There are convincing data that long-term oral therapies may be of benefit. Angiotensin-converting enzyme inhibitors (ACEi) or angiotensin receptor blockers (ARBs) should be considered in patients with evidence of depressed left ventricular systolic function and/or dilation of the left ventricle to assist in favorable remodeling (144). Captopril has been shown to reduce inflammatory infiltrates and calcification and the ARB candesartan has been shown to enhance survival and decrease inflammatory mediators in murine models of myocarditis (145,146). There are increasing data that support the use of nonselective beta blockade in patients with myocarditis. Murine models treated with beta blockade have decreased inflammation (147). Human studies clearly report the lack of beta blocker use as an independent predictor of poor prognosis (148). Therapy with aldosterone antagonists such as aldosterone or eplerenone may be considered in patients with evidence of fibrosis but they must be monitored closely for hyperkalemia if receiving concomitant ACEi or ARB therapy. Additional possible therapeutic strategies for heart failure may be found elsewhere (144). Patients with evidence of decompensated heart failure may be best managed in an intensive care setting. Significant volume overload should be treated with diuretic therapy accompanied by avoidance of significant electrolyte disturbances as this may provoke arrhythmias. Patients who show signs of poor perfusion and low cardiac output should all be managed in an intensive care setting with careful selection of inotropic agents. A more extensive management approach to patients with decompensated heart failure may be found elsewhere in this text as well in current evidence-based guideline statements (144,149).

Arrhythmias should be treated appropriately and aggressively (56). Supraventricular and ventricular tachyarrhythmias

may be seen and should be treated quickly. Ventricular arrhythmias in the setting of systolic dysfunction may require intravenous amiodarone. Despite aggressive treatment of these arrhythmias, rapid deterioration to ventricular fibrillation, especially in the very young, may occur and should be treated immediately by direct-current cardioversion. Refractory ventricular tachycardia/fibrillation may suggest the need for mechanical circulatory support (MCS). Acute or chronic conduction system disease, including complete heart block, may be seen and should be treated with temporary or permanent pacing based on the clinical scenario.

Chronic arrhythmias may persist long after the acute disease has passed, especially in the setting of myocardial fibrosis. Thus, children who recover from myocarditis, regardless of cause, should be followed indefinitely with appropriate arrhythmia surveillance. Our practice has been to perform ambulatory Holter monitoring annually at a minimum with more frequent assessment or alternative strategies such as event recorders in patients with symptoms or concerns for ongoing arrhythmia. Antibiotic agents should not be given unless a bacterial infection is suspected and appropriate cultures are obtained prior to initiating therapy.

The use of immunosuppressive and immunomodulatory agents in suspected cases or proven cases of viral myocarditis remains controversial. The routine use of immunosuppressive agents for adults with myocarditis in the United States is not recommended based on results from the Myocarditis Treatment Trial. The Myocarditis Treatment Trial analyzed the use of immunosuppressive and steroid therapy (52). Although the study was performed in adult patients, the results are potentially applicable to children. There was no difference among patients treated with azathioprine and prednisone, cyclosporine and prednisone, and conventional therapy. Immunosuppressive therapy was not beneficial in most patients with histologically confirmed myocarditis. However, there may be selected populations with chronic myocarditis that benefit from immunosuppression. Frustaci et al. have reported favorable responses in adult patients with active myocarditis, chronic heart failure, absence of viral genome in the myocardium, and positive cardiac autoantibodies when treated with azathioprine and prednisone (150). One pediatric study suggested that immunosuppression may actually result in an improvement in patients who have evidence of viral myocarditis (151). Further pediatric investigation will be required to better define this strategy.

Another important therapeutic option is the use of intravenous γ -globulin (IVIG) in children with myocarditis. This option is based on the early results of Drucker et al. (152), who investigated the use of this agent in 21 of 46 children with myocarditis. Patients who received IVIG had better left ventricular function at follow-up. However, there was no clear survival benefit. Murine data also support the use of IVIG in viral myocarditis (153). The results of the Intervention for Myocarditis and Acute Cardiomyopathy (IMAC-1) trial evaluating the use of IVIG in adults with recent myocarditis or DCM < 6 months in duration showed no benefit when compared to placebo (154). However, our recent data in the pediatric transplant population suggest there may be a role for IVIG and viral myocarditis, especially in PVB19-positive patients (82).

The use of interferon has also been proposed as a potential treatment option. Kuhl et al. reported efficacy of interferon- β treatment in myocarditis with viral clearance and prevention of progressive deterioration of left ventricular function (155). In this phase-II study, 22 consecutive patients with chronic left ventricular dysfunction and PCR-proven enteroviral or adenoviral infection were injected subcutaneously with interferon- β three times weekly for approximately 6 months, with all 22 patients demonstrating viral clearance, reduced

left ventricular dilation, and improved systolic function. D'Alto et al. (156) reported similar success with interferon- α in patients with enterovirus-induced myocarditis. No reports exist regarding interferon therapy for adenovirus.

The prognosis of acute myocarditis in newborns has been poor over the years (157–159). A 75% mortality rate was observed in 25 infants with suspected CVB myocarditis (157). Most deaths occurred in the first week of the illness. The six infants who survived had no apparent sequelae, although long-term follow-up was not reported. It is likely that other viral causes of myocarditis such as adenovirus have similar poor outcomes as infants. Older infants and children have a better prognosis, with a mortality rate between 10% and 25% in clinically recognizable cases. Has-treiter reported complete recovery in 50% of their patients (158). Twenty-five percent of the patients continued to have an abnormal electrocardiogram or chest radiograph even though they were clinically asymptomatic. Abnormalities in the resting electrocardiogram may not be seen, but may be brought out with exercise. Adult patients who recover may be asymptomatic at rest or with light exertion but may demonstrate a reduced working capacity with exercise stress testing. We suggest continued surveillance of children and adults as long-term sequelae are becoming increasingly recognized with the use of more sophisticated imaging modalities such as cardiac MRI.

Advanced Therapies Including Mechanical Support

Patients with fulminant myocarditis may progress to need for advanced therapies including MCS. Extracorporeal membrane oxygenation (ECMO) is a widely used tool for patients who have cardiorespiratory compromise as an acute support strategy (160,161). Teele et al. (65) recently reported a single-center cohort of pediatric patients with acute fulminant myocarditis and the use of ECMO as a rescue strategy in patients with end-organ dysfunction or arrhythmias with a transplant-free survival rate of 80%. With the development of newer and miniaturized devices, alternative options are now available for both short- and long-term support (162). We recently published our single-center data on the effectiveness of MCS in pediatric patients with acute fulminant and persistent myocarditis, which is the largest report of its kind in children (163). In our cohort, 16 patients were treated for myocarditis with conventional therapies plus ECMO, ventricular assist device (VAD), or both. Of these, 75% survived with seven recovering ventricular function with device removal and five went on to uncomplicated cardiac transplant. Patients without inflammation or evidence of viral infection on EMB were significantly more likely to recover. VADs are used successfully in adults with good outcome (164). Their use will increase in the pediatric population given the increasing availability of devices and the potential need for sustained support in select patients. Furthermore, these devices allow time for myocardial recovery and favorable remodeling of key proteins that may be damaged in viral myocarditis (165).

Vaccination

Vaccination has been used successfully to prevent diseases. The efficacy of the polio vaccine has led to the suggestion that a broadly specific enteroviral vaccine, or at least a CVB-specific vaccine, could be beneficial for reducing the incidence of myocarditis or DCM. Development of CVB3 vaccine has afforded protection in mice but no human studies have been conducted (166).

The possibility of success in this regard is supported by the study of EFE. This form of DCM was the most common form

identified in children until the late 1960s, with an incidence of 1 in 5,000 live births in the United States. Since that time, the incidence has declined significantly. Mumps virus genomic RNA sequences were found in 90% of myocardial samples from EFE patients analyzed (49) (Fig. 56.10). Thus, EFE may have resulted from persistent in utero mumps infection of the myocardium. The mumps virus vaccine has all but eliminated this form of DCM. Although a CVB-specific vaccine may reduce the incidence of myocarditis, other viruses, particularly adenovirus, are potential etiologic agents.

Susan W. Denfield

Cardiomyopathies are defined as diseases of the myocardium associated with cardiac dysfunction (1). Per the World Health Organization (WHO), restrictive cardiomyopathy (RCM) is characterized by restrictive filling and reduced diastolic volume of either or both ventricles with normal or near-normal systolic function and wall thicknesses. Increased interstitial fibrosis may be present. It may be idiopathic or associated with another disease.

“Contemporary Definitions and Classification of the Cardiomyopathies” have been proposed by a consensus panel organized by the American Heart Association (AHA) to draw attention to the rapid advancement of molecular genetics in cardiology (2). The AHA consensus statement defined primary RCM as a rare form of heart disease characterized by “normal or decreased volume of both ventricles associated with biatrial enlargement, normal left ventricular wall thickness and atrioventricular valves, impaired ventricular filling with restrictive physiology, and normal (or near normal) systolic function” (2). At that time, the panel placed RCM in a “mixed” cardiomyopathy category because the causes of the diseases resulting in RCM were believed to be predominantly nongenetic.

This chapter reviews the epidemiology, etiologies including known genes and associated syndromes, pathology, pathophysiology, clinical presentation, diagnostic evaluation, differential diagnosis, outcome, and management of pediatric patients with RCM.

EPIDEMIOLOGY

Of the four types of cardiomyopathy categorized by the WHO, dilated, hypertrophic, restrictive, and arrhythmogenic right ventricular cardiomyopathy, restrictive cardiomyopathy is the least common (1). In children, RCM accounts for 2.5% to 5% of the diagnosed cardiomyopathies (3–7). In the Australian-based study by Nugent et al., RCM accounted for 2.5% of the cardiomyopathies diagnosed in children <10 years of age (6). This is similar to the two-region United States–based study by Lipshultz et al., who reported that RCM or other specified types (not dilated or hypertrophic) accounted for 3% of the cardiomyopathies in children <18 years of age (7). Three different single institution studies reported 5%, which may have been due to referral bias (3–5).

Overall, the incidence of cardiomyopathies is higher in children <1 year of age when all types of cardiomyopathy are considered (6,7). RCM may be an exception. In the Nugent et al. study, the incidence of all types of cardiomyopathy except restrictive declined rapidly after infancy to their maximum study age of 10 years (6). In the studies of RCM in children, the average age at the time of diagnosis was 6 years with median of 5 years and a range from 0.1 to 19 years (3–5,8–33). Only two of the patients were 19 at the time of diagnosis with the remainder <18 years old. At the time of diagnosis, 8% were

1 year of age or younger, with 12% between the ages of 12 and 19 years. Whether this apparent difference in usual age of onset is due to case ascertainment or true differences in the disease onset is unknown.

Gender differences have also been reported in cardiomyopathies. Beyond infancy, boys had a higher incidence of cardiomyopathy than girls in the study by Lipshultz et al. (7). Only hypertrophic and unspecified cardiomyopathies occurred with higher frequency in boys in the Nugent et al. study, with RCM occurring with equal frequency in boys and girls (6). Of the 205 subjects with RCM in whom gender was reported, 54% were female (3–37).

Sporadic and familial cases of RCM are reported. Approximately 30% of patients, in whom family history was reported, had a positive family history (3–37).

GENETICS

Mutations in at least 10 genes have been associated with the RCM phenotype and include sarcomeric and nonsarcomeric gene defects (Table 57-1) (38–51).

Sarcomeric Protein Gene Defects

Troponin I mutations have been identified in patients with RCM and hypertrophic cardiomyopathy (HCM) (39). Both the RCM phenotype and the HCM phenotype can be expressed in the same family. This indicates that idiopathic RCM can be part of the clinical expression of sarcomeric contractile protein disease. The diversity of the phenotypic expression of troponin mutations in families suggests that additional genetic or environmental factors or both play a role in disease expression. *De novo* mutations and autosomal dominant transmission have been documented in RCM patients and their families (39).

Kaski et al. (44) reported a small series of pediatric patients with RCM; 4 of the 12 patients had a positive family history of cardiomyopathy, but the phenotypes varied and included restrictive, dilated, and left ventricular noncompaction forms. Gene mutations were found in troponin I (TNNI3), troponin T (TNNT2), and alpha cardiac actin. Peddy et al. reported an infant who presented with malignant arrhythmias and RCM and had a *de novo* mutation of cardiac troponin T (45).

Ware et al. (46) described a mutation in a beta-myosin heavy chain gene in an infant with RCM. Mutations in the beta-myosin heavy chain account for approximately 40% of mutations found in HCM in adults (47). The overlapping genotypic–phenotypic correlations are also evident in a report by Olson et al. (48). The proband was a child with a myosin light-chain mutation resulting in a cardiomyopathy with midcavitary hypertrophy and restrictive physiology that was inherited in an autosomal recessive pattern. His two older brothers had cardiomyopathy with dilated atria, both

TABLE 57.1 Gene Mutations Reported in Association with RCM

Sarcomeric Mutations	Nonsarcomeric Mutations
Troponin I	Desmin
Troponin T	RSK2 (Coffin-Lowry syndrome)
Alpha cardiac actin	Lamin A/C (Emery-Dreifuss)
Myosin-binding protein C	Transthyretin (amyloidosis)
Beta-myosin heavy chain	
Myosin light chain	

of whom died related to thrombotic complications. Clinically unaffected family members were either heterozygotes or lacked the mutant allele. Additional gene mutations are likely to be found with ongoing genetic studies.

Nonsarcomeric Protein Gene Defects

Desmin and RSK2 mutations have been reported in children with RCM, while lamin A/C and transthyretin mutations have been reported to cause an RCM phenotype in adults. A Danish kindred has been documented in whom children have been identified as carriers of the familial transthyretin methionine 111 mutation, but none of the kindred has manifested amyloid-associated RCM in childhood (49), although adults in the family have developed RCM. The transthyretin Ile 122 mutation resulting in RCM with amyloidosis has only been reported to manifest RCM in adulthood, as well (40).

Desmin is a myofibrillar protein that is the chief intermediate filament of skeletal and cardiac muscle (41). It maintains the structural and functional integrity of the myofibrils and functions as a cytoskeletal protein linking Z bands to the plasma membrane. Mutations in the desmin gene may cause RCM with or without skeletal myopathy and with or without conduction system disease (41,42,50,51). The inheritance pattern is usually autosomal dominant. Sporadic mutations have also been identified (41).

Coffin-Lowry syndrome is an X-linked disorder caused by mutations in the RSK2 gene on chromosome Xp22.2 (43). It is characterized by developmental delays, short stature, facial dysmorphism, and progressive skeletal deformities. Cardiac anomalies are reported in approximately 14% of affected males with cardiomyopathy being one of the rare but reported cardiac abnormalities, including one patient with a restrictive phenotype (33).

Emery-Dreifuss muscular dystrophy was first described as an X-linked disorder caused by mutations in the gene encoding for emerin on chromosome Xq28 (38). However, it can also be an autosomal disorder caused by mutations in the gene encoding for lamin A and lamin C (LMNA) on chromosome 1q21.2–q21.3 (38). Both variants of the disease can cause cardiac abnormalities including dilated cardiomyopathy, atrial and ventricular arrhythmias, conduction abnormalities, and sudden death. Sanna et al. (38) reported on the cardiac features of Emery-Dreifuss caused by lamin A/C gene mutations, including one adult patient with a restrictive phenotype. The RCM phenotype has not been reported in children with Emery-Dreifuss to date.

Alstrom syndrome is characterized by cone-rod dystrophy resulting in progressive visual impairment, photophobia

and nystagmus, obesity, progressive sensorineural hearing impairment, dilated or RCM, insulin resistance, and multiple organ failure (52). ALMS1 is the only gene currently known to be associated with the syndrome and is estimated to be detected in 25% to 40% of individuals.

Mulibrey nanism is an autosomal recessive disease caused by mutations in the TRIM37 gene on chromosome 17q22–q23 encoding the peroxisomal TRIM37 protein of unknown function (53). Congestive heart failure and pericardial constriction were diagnosed during infancy in 12% and 6% of the patients, respectively, in a report by Karlberg et al. (53). Characteristic craniofacial features included scaphocephaly, facial triangularity, high and broad forehead, and low nasal bridge in more than 90% of the patients. Other findings included a peculiar high-pitched voice (96%), yellowish dots in ocular fundi (79%), cutaneous naevi flammei (65%), hepatomegaly (45%), and fibrous dysplasia of long bones (25%). Mild muscular hypotonicity (68%) was the only neurologic abnormality. Although more typically associated with constrictive pericarditis (CP), a mixed constrictive–restrictive phenotype has been described as not all patients have improved with pericardiectomy, and myocardial hypertrophy and fibrosis have been reported (54,55).

ETIOLOGIES

RCM has multiple causes and may result from myocardial diseases including noninfiltrative or infiltrative processes, storage diseases, endomyocardial diseases, myocarditis, and following cardiac transplantation (56) (Table 57.2). The pathology and histology vary with the underlying disease process. The most common etiology of RCM worldwide is secondary to endomyocardial fibrosis (EMF). EMF is estimated to affect 10 million people worldwide, occurring most often in children and adolescents (57,58). In adults outside the tropics, amyloidosis is the most common cause of RCM (59). One case of cardiac amyloidosis has been reported in a pediatric patient (5). In the pediatric population, outside the tropics, idiopathic RCM is probably the most common cause of RCM based on reported cases in the literature (3–37).

Endomyocardial Disease

EMF was first described by Davies in 1948 (60). It occurs most frequently in tropical and subtropical Africa, particularly Uganda and Nigeria. However, it is also found in tropical and subtropical regions throughout the world. It is occasionally seen in temperate climates, usually in individuals who previously lived in tropical areas. The etiology or etiologies remain unknown. Hypereosinophilia, likely related to parasitic infections, has occurred in some patients. However, there does not appear to be an increased prevalence of parasitic infections in patients with EMF. Autoimmunity, genetic, dietary, and environmental chemical factors have all been implicated in the development of EMF (58).

The disease occurs most often in children to young adults (57,58,61). Familial occurrence, and in some countries a high incidence in some ethnic groups, suggests a possible genetic predisposition (57,58). In a rural area of Mozambique, the overall prevalence of EMF was 20% in the population, but increased to 28% when two family members were affected and 39% when three or more family members were affected (57).

The disease is most commonly biventricular, followed by pure left ventricular involvement approximately 40% of the time and purely right ventricular in 10% (62). The symptom

TABLE 57.2 Causes of Restrictive Cardiomyopathies in Children and/or Adults

Myocardial	Endomyocardial
Idiopathic	Endomyocardial fibrosis
Familial/genetic	Hypereosinophilic syndrome (Löffler endocarditis)
Scleroderma	Endocardial fibroelastosis
Myocarditis	Carcinoid
Cardiac transplant	Metastatic cancers

Cystinosis (possibly)	
Emery-Dreifuss	
Coffin-Lowry syndrome	

complex varies with the site or sites of involvement. Symptoms from pulmonary venous congestion result from left-sided disease, while right-sided disease results in signs and symptoms from systemic venous congestion. Involvement of the mitral or tricuspid valve apparatus can result in significant valvular regurgitation. Medical and surgical therapy is palliative.

The histology of EMF is characterized by endocardial fibrosis of variable thickness. Histologic changes occur in predominantly three areas: the left ventricular apex, the mitral valve apparatus, and the right ventricular apex that may extend to the supporting structures of the tricuspid valve. In severe cases, the process may extend to the outflow tracts. Small patches of fibroelastosis may occur in the outflow tracts, but the elastin component is thought to be secondary and not a primary part of the process. Cellular infiltrates are not prominent. Eosinophilia is not typically a prominent feature in contrast to Löffler endocarditis.

Hypereosinophilic Syndrome/Löffler Endocarditis

Löffler endocarditis or the hypereosinophilic syndrome (HES) is similar to EMF in many respects. There is continued debate whether they are variants of the same disease. Although there are pathologic and clinical similarities, there are important contrasts. HES is typically seen in temperate climates. It is more common in adult males. Hypereosinophilia is present. HES includes persistent eosinophilia with 1,500 eosinophils/mm³ for at least 6 months or until death with evidence of organ involvement. Usually, in HES, various organs besides the heart are involved and may include the lungs, bone marrow, and brain (63). The cause of the eosinophilia is usually unknown,

but may be leukemic or secondary to parasitic, allergic, granulomatous, hypersensitivity, or neoplastic disorders (64).

Cardiac histologic findings include variable degrees of eosinophilic myocarditis (not characteristically seen in EMF), inflammatory reaction in the small intramural coronary vessels with thrombosis and fibrinoid change, and endocardial mural thrombosis and fibrotic thickening (62).

The clinical picture may include weight loss, fever, cough, rash, and heart failure. Systemic embolism is frequent. Death is usually secondary to the cardiac manifestations of the disease. Therapy for the hypereosinophilia may include corticosteroids, hydroxyurea, or vincristine, but this area of therapy is usually not directed by a cardiologist. Cardiac therapy has included digoxin, diuretics, afterload reduction, and anticoagulation. Surgical approaches have included mitral and/or tricuspid valve repair or replacement and excision of fibrotic endocardium and may be useful for symptom palliation of intractable heart failure. However, pediatric case reports and case series of HES and EMF patients report a relatively high reoperation rate secondary to dysfunction of the mechanical or bioprosthetic valves with recurrent thrombosis, fibrosis, or tearing despite anticoagulation (65,66). Significant cardiac symptoms may persist (class II to IV) (66).

Infiltrative and Storage Diseases

Several metabolic disorders with specific enzyme deficiencies can result in RCM, including lysosomal disorders such as Hurler syndrome, Gaucher disease, and Fabry disease and glycogen storage diseases that can be lysosomal disorders or result from cytoplasmic enzyme deficiencies.

Hemochromatosis may be a primary or secondary disease resulting from iron overload with subsequent dysfunction of multiple organs including the heart. Either RCM or more commonly dilated cardiomyopathy may result from hemochromatosis.

Nephropathic cystinosis is an autosomal recessive disease that leads to multiorgan failure from intracellular accumulation of cystine (67). Dixit and Greifer reported one patient followed from infancy who developed a cardiomyopathy with restrictive features in adulthood and had extremely high cystine levels in the myocardium. Owing to the patient's history of renal failure, renal transplantation, and hypertension, the exact etiology of the restrictive physiology is uncertain.

Sarcoidosis is a noncaseating granulomatous disorder that is more common in adults than in children. The granulomatous inflammatory process can affect the heart and result in RCM. Systolic dysfunction, pericarditis, conduction system disease, and sudden death may also occur. Although a common cause of RCM in adults, amyloidosis as a cause for RCM in pediatrics has been reported in only one case (5).

Drugs and Therapeutic Agents

Anthracyclines, serotonin, methysergide, ergotamine, mercurial agents, busulfan, and chloroquine have been reported to cause RCM (68–72). Mediastinal radiation has also resulted in RCM (73).

Idiopathic

Outside the tropics, the idiopathic form of RCM is probably the most common form in children. Although the family history is positive in only approximately 30% of this population, a genetic basis or predisposition for the development of the disease is likely.

Figure 57.1. The left atrium (LA) is massively dilated, dwarfing the size of the left ventricle (LV) in this autopsy specimen from a patient with restrictive cardiomyopathy.

PATHOLOGY

Figure 57.1 demonstrates the typical appearance of a heart from a patient with idiopathic RCM. The left atrium dwarfs the left ventricle. The left ventricular cavity size is normal with no appreciable left ventricular hypertrophy. In the vast majority of cases, the hearts are otherwise structurally normal, although there have been rare reports of patients who also have atrial septal defects or small hemodynamically insignificant ventricular septal defects (11,30). The histology in idiopathic RCM is nonspecific revealing varying degrees of fibrosis and myocyte hypertrophy (3,34,37). The histology may vary with the underlying disease process.

PATHOPHYSIOLOGY

Diastolic function is primarily affected by ventricular compliance/stiffness and relaxation. In the normal heart, the phase of rapid or early filling occurs as the left ventricular pressure drops below that in the left atrium, just after the mitral valve opens, and accounts for most of the ventricular filling (74,75). The duration of the next phase, called diastasis, is variable and heart rate dependent, permitting <5% of filling. The last phase of diastole is atrial systole and accounts for approximately 15% of normal ventricular filling. In the classic description of RCM, ventricular filling is completed in early diastole with little or no filling in late diastole. In this model, restrictive physiology results from increased myocardial stiffness with decreased compliance, causing a marked ventricular pressure rise with small changes in volume.

The earliest phase of clinical diastole is isovolumic relaxation which is an active energy-requiring process for the uptake of calcium ions into the sarcoplasmic reticulum. Ischemia and hypertrophy can both result in abnormal relaxation owing to changes in calcium uptake. Gewillig et al. reported on six children with RCM who by catheterization and echocardiography had parameters suggesting delayed relaxation as well as restrictive filling as the mechanisms for the RCM. In their patients, early filling contributed approximately 56%, middiastolic filling 28%, and atrial filling 16% to total ventricular filling. They suggested that the restrictive hemodynamics were caused by dysfunction and delay of active relaxation of the ventricle rather than increased intrinsic stiffness of the ventricular wall (12).

It is likely that, as diastolic diseases become better understood, RCM is likely to result from abnormal stiffness or

abnormal relaxation or both depending on the underlying cause of the disease and disease progression.

CLINICAL PRESENTATION

In children, heart failure signs and symptoms from RCM are often confused with other diseases. Common presenting symptoms often appear to be pulmonary related. Children with RCM frequently have dyspnea on exertion and older children may complain of exercise intolerance. A history of "recurrent lower respiratory tract infections" or "asthma" is common. Referral to a cardiologist eventually occurs when cardiomegaly is noted on chest x-ray.

Additional common reasons for referral are abnormal physical exam findings. Patients who have ascites, hepatomegaly, and edema are frequently referred to a gastroenterologist first. Referral to the cardiologist occurs when additional cardiac signs or symptoms occur, a chest x-ray is noted to be abnormal, or no specific gastrointestinal etiology is found for the edema and hepatomegaly. Earlier referral to a cardiologist occurs when the presenting sign is an abnormal heart sound, such as murmur, gallop, or loud P2.

Syncope accounts for approximately 10% of the presenting complaints. Syncope in this patient population may be related to ischemia, arrhythmias, or thromboembolism (11,12). Ischemia and/or arrhythmias may be the most common causes of syncope and sudden death in this patient population (7,37). In one case, no definitive mechanism for syncopal episodes was found, an arrhythmia was ruled out, and there were no ischemic changes on treadmill testing (4).

Two children had sudden cardiac death as their presentation at ages 6 and 16 years, presumably secondary to familial RCM as there were 13 other affected family members in five generations (14).

A positive family history was an infrequent reason for referral in the published reports.

Physical Examination

Common findings include a gallop rhythm and a loud P2. Hepatomegaly, ascites, and edema are also commonly found.

DIAGNOSTIC STUDIES

Electrocardiograms

The electrocardiogram is extremely useful in screening for RCM. Approximately 98% are abnormal (3–12,14–27,30,32,37). Figure 57.2 is a representative example. The most common abnormalities are right and/or left atrial enlargement; however, ST segment depression and ST-T wave abnormalities are frequently present. Right and/or left ventricular hypertrophy can also be seen as well as conduction abnormalities.

Holter

Holter evaluations can also be useful, not only for rhythm evaluation but also for ST segment analysis. Rivenes et al. (11) reported Holter results in 12 patients, 8 of whom had ischemic changes with ST segment depression from 3 to 12.7 mm, most evident at higher heart rates. In one patient, the development of ventricular tachycardia was preceded by chest

Figure 57.2. ECG from a 2-year-old with restrictive cardiomyopathy demonstrating sinus rhythm with biatrial enlargement, qR pattern in the right chest leads, and ST segment depression and T wave inversion in the inferolateral and lateral chest leads.

pain and ST—segment depression of 8.2 mm. The patient had been hospitalized at the time due to recurrent chest pain. Case reports have also demonstrated ischemic or infarct patterns on ECG and autopsy, and in some children, chest pain related to the ischemia was identified, suggesting this is an important cause of morbidity and mortality in this patient population (8,11,17,18). Hayashi et al. (37) did not find coronary abnormalities by catheterization in their RCM patients with ST segment depression, nor did they find perfusion defects on exercise testing in the majority of their patients leading them to conclude that arrhythmia is a more common cause of sudden death than ischemia-mediated events. However, the most likely cause of ischemia in this patient population would be relatively diffuse hypoperfusion of the subendocardial myocardium due to the high diastolic filling pressures impairing coronary perfusion, and not coronary abnormalities *per se*. This type of hypoperfusion, if diffuse, would also be harder to detect by exercise myocardial perfusion studies. Cardiac MRI with delayed enhancement might be a better tool to further investigate this mechanism.

Of the pediatric studies reporting arrhythmias, approximately 15% of the patients had arrhythmias and/or conduction disturbances (3,4,9–11,21,25,27,30,34,37). Atrial flutter was the most commonly reported arrhythmia. High-grade second-degree and third-degree heart block were the next most commonly reported rhythm disturbances. Atrial fibrillation and atrial tachycardias, Wolff-Parkinson-White syndrome with supraventricular tachycardia, symptomatic sinus bradycardia requiring pacing, and ventricular tachycardia and torsade were also reported.

Chest Radiographs

The chest x-ray appears to be a useful screening test, as it is abnormal in approximately 90% of cases (3–12,14–24,30,37). Cardiomegaly and pulmonary venous congestion are the most common abnormalities.

Echocardiography

The echocardiogram is usually diagnostic (Fig. 57.3). On 2-D imaging, classic cases demonstrate markedly dilated atria, often dwarfing the size of the ventricles. Typically, there is normal or nearly normal left ventricular systolic function and absence of significant hypertrophy or dilation. However, based on studies reporting systolic functional parameters, as many as 30% may present with or develop a depressed shortening or ejection fraction (3,10,12,30). Reported shortening fractions have been as low as the low 20s with ejection fractions as low as the upper 30s. In addition, as many as 40% have or develop mild, and sometimes progressive, left ventricular hypertrophy (3,4,10,12,30). Variable patterns of hypertrophy have been reported including concentric, “mid septal bulge,” apical hypertrophy, and “atypical hypertrophy.” It is possible that the subset of patients with hypertrophy may have a troponin I mutation. The “mixed restrictive/hypertrophic phenotype” can result in a confusing clinical picture in terms of diagnosis, RCM versus HCM, and optimal therapeutic approaches. During 2-D imaging, thrombi should be specifically sought. Thrombotic and embolic events have been described in approximately 20% of pediatric patients with idiopathic RCM reported in nine studies (3,4,9,10,12,26,30,76,77). In HES and EMF, there may be obliteration of the apex by thrombus. In HES and EMF, the atrioventricular valve apparatus are frequently involved in the pathologic process with thickening of valve leaflets and decreased excursion, particularly of the mitral valve. In idiopathic RCM, the valves are typically normal in appearance. Pericardial thickening on 2-D evaluation would suggest CP and not RCM.

Doppler patterns of diastolic dysfunction have been well characterized in adults and pediatric data have also been reported (78,79). Although many studies have characterized Doppler findings in adults with RCM, only a few pediatric studies have described Doppler findings in children with RCM

Figure 57.3. Echocardiogram from a child with RCM. Panel A demonstrates severe biatrial enlargement, dwarfing the size of the ventricles. Panel B demonstrates mitral inflow with an increased E to A ratio and a shortened deceleration time. RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle.

(9,10,12,27). Some of the children in some of these studies did not have complete Doppler data as all the pediatric studies have been retrospective. In the patients described, the findings consistent with restrictive filling and increased left ventricular end diastolic pressure included elevated E/A ratios, short mitral deceleration times, increased pulmonary vein atrial reversal velocity and duration, and pulmonary vein atrial reversal duration greater than mitral A duration (9,10,27). Restrictive hemodynamics are typically thought to be caused by increased ventricular wall stiffness; however, idiopathic RCM may also result from disorders of delayed active relaxation. The Gewillig et al. (12) study described six children with idiopathic RCM whose Doppler profiles were consistent with restrictive filling with elevated E/A ratios and shortened deceleration times, but who also had parameters suggesting dysfunction and delay of active relaxation of the ventricle. In their patients, mitral inflow patterns revealed a prominent mitral L wave with middiastolic filling accounting for approximately 28% of total ventricular filling. The left ventricular pressure curve showed a small but steady decline during middiastolic filling on cardiac catheterization, implying that the driving force for filling was “ventricular suction” and not increased left atrial pressure. Friedberg and Silverman have reported on the systolic (S) to diastolic (D) duration ratio in children with heart failure secondary to RCM (80). Children with RCM had

an elevated S/D ratio compared to controls due to a prolongation of systole with shortened diastole. This was not specific to heart failure in RCM, however, as they found similar results in children with dilated cardiomyopathy.

In adults, Doppler tissue imaging has been used to help differentiate between RCM and CP (81,82). A mitral E' of ≥ 8 cm/s was highly sensitive and specific for differentiating CP from RCM (82). This cutoff point needs further evaluation in children.

Cardiac Catheterization and Endomyocardial Biopsy

Cardiac catheterization is an important part of the evaluation in patients with RCM and should be performed at the time of diagnosis. Catheterization can help differentiate between RCM and CP, although virtually all hemodynamic features can overlap (83).

Both diseases typically have an early diastolic dip and subsequent plateau pattern, also called the square root sign (Fig. 57.4) (62,83). In “classic” RCM, the left ventricular end diastolic pressure, left atrial pressure, and pulmonary capillary wedge pressure are markedly elevated and at least 4 to 5 mm Hg (preferably 10 mm Hg) greater than the right atrial pressure and right ventricular end diastolic pressure. In cases

Figure 57.4. Pressure tracing during cardiac catheterization in a patient with restrictive cardiomyopathy (RCM) demonstrating the dip and plateau or square root sign that may be seen in either RCM or constrictive pericarditis. LV, left ventricle; RV, right ventricle.

in which the pressures are essentially equal, volume loading may bring out the differences in pressure between the right and left sides.

Pulmonary hypertension is frequently present at the time of initial catheterization in addition to elevated left and/or right ventricular end diastolic pressures (3,10,27,29–31,34–36). The initial pulmonary vascular resistance index (PVRI) may be normal to as high as 24 U m^2 (3,10,27,29–31,34–36). In studies providing follow-up data 0.3 to 8 years after presentation, the PVRI ranged from normal to 30 U m^2 (3,30,31). The pulmonary vasculature frequently remains reactive, however (31,35,36). The Kinberling study suggested the best response was to nitric oxide (31). However, in the study by Weller et al. (30), 40% were precluded from orthotopic heart transplant due to an elevated and nonreactive pulmonary vascular resistance at the time they were evaluated for cardiac transplantation. None of the studies predicted when or in whom fixed pulmonary vascular resistance would develop.

Endomyocardial biopsies generally are nondiagnostic, showing varying degrees of fibrosis and hypertrophy (3,34,37). Increased numbers of mitochondria are seen in some patients as is an increase in glycogen (3,5,10). One case of cardiac amyloidosis in a pediatric patient has been reported, but endomyocardial biopsy is rarely diagnostic of a specific etiology (3,5,10,12,34,37). Desmin myopathy has been seen in skeletal muscle biopsy and cardiac tissue, leading to an etiologic diagnosis (26,41). This can signify impending skeletal myopathy and/or conduction system disease and should be evaluated for in any biopsy tissue obtained. However, finding a specific etiology by endomyocardial biopsy is uncommon, and the procedure is not risk free in these tenuous patients (3,19,34).

DIFFERENTIAL DIAGNOSIS

CP is the disease process that is most commonly confused with RCM. The clinical presentation of patients with RCM and CP can be very similar as can results of tests used to differentiate between the two. Table 57.3 summarizes the findings of typical test results for the two disease processes; however, considerable overlap may occur. In most cases, noninvasive studies and hemodynamic catheterization without an endomyocardial biopsy can distinguish between RCM and CP. However, in limited cases, endomyocardial biopsy may be necessary to help distinguish CP from RCM. The findings in CP are nonspecific. The absence of myopathic findings lends support to the diagnosis of CP, while the presence of myopathic changes suggests RCM, but infrequently identifies a specific diagnosis in RCM (3,10,12,34,37). Children with RCM or CP are hemodynamically fragile. Case series and reports in children with RCM have reported deterioration and death during or shortly after catheterization and biopsy (4,19,34). Therefore, careful consideration of the risk–benefit ratio of the information that is likely to be obtained by the biopsy should be undertaken prior to catheterization. Rarely, exploratory thoracotomy is necessary to differentiate CP from RCM, as there continue to be cases in which the hemodynamic profile has so much overlap that thoracotomy is necessary for diagnosis. Henein et al. (84) have suggested that, in those cases in which pericardial disease is found, the term restrictive pericarditis should be applied. Wang et al. (85) reported a case of a child with mixed CP and RCM features. Features consistent with CP included pericardial calcification and a lateral mitral annular tissue Doppler

TABLE 57.3 Restrictive Cardiomyopathy Versus Constrictive Pericarditis

	RCM	CP
ECG finding		
Atrial enlargement	Nearly universal	May be present
LVH and/or RVH	Common	Usually absent
Low-voltage QRS	Unusual	Common
ST-T wave abnormality	Common	Common
Chest x-ray		
Calcification	Absent	≤21%
Echocardiogram		
Pericardial thickening	Absent	May be thickened
Atrial dilation	Marked	May be enlarged
Wall thicknesses	Normal to mild hypertrophy	Usually normal
Systolic function	Normal to depressed	Normal
Septal bounce	Absent	Usually present
Doppler		
Respiratory flow changes	Occasional	Usually marked
Gated MRI/CT		
	Normal pericardium	Usually thickened
Cardiac catheterization		
	PWP and LVEDP may exceed RAP and RVEDP by >4 mm Hg. RVSP often >50 mm Hg	RAP = PWP, RVEDP = LVEDP usually within 4 mm Hg RVSP usually <50 mm Hg
RV endomyocardial biopsy		
	Usually abnormal (frequently nonspecific)	Usually normal
Thoracotomy		
	Normal pericardium	Usually abnormal pericardium

CP, Constrictive pericarditis; LVH, left ventricular hypertrophy; RVH, right ventricular hypertrophy; PWP, pulmonary wedge pressure; LVEDP, left ventricular end diastolic pressure; RAP, right atrial pressure; RVEDP, right ventricular end diastolic pressure; RVSP, right ventricular systolic pressure; RV, right ventricular.

velocity of 18 cm/s; however, endomyocardial biopsy showed myocyte hypertrophy and fibrosis, thought to be more consistent with a cardiomyopathic process. Pericardiectomy resulted in symptomatic improvement despite the myopathic features on endomyocardial biopsy even though the calcified pericardium could not be completely resected. If CP is identified, pericardiectomy may be curative and is the treatment of choice. However, in patients with RCM, exploratory thoracotomy is not a benign procedure, has no therapeutic benefit, and may result in death (30). Therefore, every effort should be made to establish the diagnosis of RCM without exploratory thoracotomy.

Brain natriuretic peptide (BNP) has been used to help differentiate CP from RCM in adults (86,87). In a small case series of adults by Leya et al. (87), all patients with CP had BNPs that were <200 pg/mL and were statistically significantly less than those with RCM. The lowest BNP in the RCM group was 639 pg/mL. Subsequent studies in adults have found statistically significant differences in BNP levels between those with CP and those with RCM, but significantly more overlap was seen in the BNPs between groups, particularly if the CP was secondary to prior cardiac surgery or radiation therapy rather than a primary CP, making the BNP less definitive for differentiating between CP and RCM (86,87).

Cardiomyopathies may be difficult to classify as overlapping phenotypes occur (3,10,12,30). Because some children with RCM may have some degree of left ventricular hypertrophy (3,4,10,12,30), confusion may arise as to whether the patient has RCM versus HCM, that is, the "mixed restrictive/hypertrophic phenotype." Other patients with HCM may have very dilated atria with restrictive physiology. Since a variety of phenotypes can be seen in the same family with the same gene defect, it is not surprising that phenotypes sometimes overlap. This is of more than semantic importance as children with HCM with restrictive physiology have a better prognosis than children with "pure" RCM, but not as good a prognosis as those with "pure" HCM (88). In addition, the Maskatia et al. study suggests that children with HCM and restrictive physiology have a long-term survival that is equivalent to average post-heart transplant survival in children. Therefore, listing in a number of these patients may be delayed longer than listing for "pure" RCM (89). There is also evidence of phenotypic overlap between RCM and noncompaction cardiomyopathy (90–92). Patients with dilated cardiomyopathy can also develop restrictive physiology (29).

OUTCOME

The prognosis in children with RCM is poor (3–5,8,9,11,12,29,34,37). Approximately half of the children die or have transplantation within 2 to 3 years of diagnosis. The prognosis in RCM appears to be significantly worse than in patients with HCM or dilated cardiomyopathy in whom the 2-year mortality rates are reported to be 12.7% and 13.6%, respectively (7). In RCM, heart failure–related deaths are the most common. Sudden cardiac death has also been reported to be a common cause of death in children with RCM (11,37). In the study by Rivenes et al. (11), sudden cardiac death occurred in 28% of children with an annual mortality rate of 7%. This is comparable to a 31% incidence of sudden death in children with HCM reported by Maron et al. (93). Sudden death occurred in 14% of the patients reported by Russo and Webber (34) and in 33% in the Hayashi study (37).

Factors associated with poor prognosis have not been consistent between studies. Some studies suggest an increased risk for death from heart failure in the presence of cardiomegaly and pulmonary venous congestion on chest x-ray, age younger

than 5 years, thromboembolism, and elevated PVRI (9,10,30). However, Russo and Webber did not find age or presence or absence of heart failure symptoms at presentation to be prognostic (34). They found that higher end diastolic pressures and larger left atrial:aortic ratios correlated negatively with survival. Children with heart failure are also at risk from ischemic complications as well (11). When comparing survival with RCM versus survival after transplant, it is evident that transplant results in longer survival in the majority of cases (30).

MANAGEMENT

There was no consistent approach to therapy in the studies reviewed. Various medications were given in various combinations including diuretics, digoxin, afterload reducing agents, calcium channel blockers, and beta-blockers. Due to the small number of patients in each study and the lack of uniformity of treatment within studies, the benefits or risks of these therapies could not be determined. Bengur et al. (94) reported that captopril lowered the aortic pressure by 24% without an increase in cardiac output, when administered during cardiac catheterization to four pediatric patients with RCM. They suggested that captopril should not be used in patients with RCM. However, in the studies that reported the use of ACE inhibitors, acute decompensation was not reported, nor was therapeutic or symptomatic benefit reported (3,4,10,27,30,31,37). Modulation of neurohumoral activation by ACE inhibitors may affect fibroblast activity, interstitial fibrosis, intracellular calcium handling, and myocardial stiffness. In adults with diastolic heart failure, the use of ACE inhibitors has been suggested, but data are limited in adults as well (95). The risks and benefits of ACE inhibitors in pediatric RCM remain to be determined.

In adults with diastolic dysfunction, tachycardia is poorly tolerated; therefore, beta-blockers or some calcium channel blockers have been suggested as part of the treatment regimen (95). In the pediatric article by Rivenes et al. (11), beta-blocker therapy was suggested to blunt rapid heart rates in their patient population in whom significant ST segment depression was noted at higher heart rates. Subsequently, three children <5 years old were reported who were begun on propranolol ($n = 2$) or metoprolol ($n = 1$) and who did not tolerate beta-blocker therapy (96). In the first patient, episodes of pallor, weakness, and listlessness occurred. The patient was on telemetry and no arrhythmias were documented, nor were neurologic sequelae seen. The episodes stopped when propranolol was discontinued. The second patient developed staring spells and profound diaphoresis. One episode occurred while the patient was in the hospital; it was terminated with the administration of a high dextrose infusion (D50) before a blood glucose was obtained. The propranolol was discontinued and the episodes stopped. The patient who received metoprolol became irritable and restless after 2 to 3 days on the medication with some improvement initially after stopping the drug. Further studies are needed to determine the role of beta-blocker therapy in this disease.

At present, medical therapy remains supportive and should be started with the patient hospitalized due to the fragile nature of these patients. Diuretics are useful in patients with signs and symptoms of systemic or pulmonary venous congestion. Overdiuresis should be avoided because these patients are sensitive to alterations in preload. Due to the 20% incidence of thromboembolic events, antiplatelet therapy or anticoagulants should be administered.

Since current medical therapy appears to be ineffective, the development of pulmonary hypertension is common and mortality is high, cardiac transplantation is the definitive

therapy. Outcomes in children transplanted for RCM are comparable to children transplanted for other forms of heart disease (31,35,36,97). Although some untransplanted patients may remain relatively well for over 10 years (34), this is an unpredictable minority. Most patients should be evaluated and listed for transplantation "early"; however, the definition of "early" remains controversial (11,34–35,97). Patients should undergo cardiac catheterization at the time of diagnosis with testing for pulmonary vasoreactivity if the PVRI is >6 U·m² or the transpulmonary gradient is >14 to 15 mm Hg. In many patients, the resistance can be lowered, and successful orthotopic transplants have been performed in children whose PVRI was above 9 U·m², as long as they demonstrated pulmonary vascular bed reactivity (35,36). Some children may benefit from continuous infusion of prostacyclin while awaiting determination of the best transplant strategy, that is, orthotopic versus heterotopic versus heart–lung (35). Orthotopic heart transplant is the preferred transplant since survival is better than heart–lung transplant and more feasible than heterotopic transplant in small children, although heterotopic heart transplantation has been performed in small children with RCM (35,98). When pulmonary vasodilator therapies are used, careful monitoring for the development of pulmonary edema is necessary as the left atrial pressure may rise, negating the benefit of the fall in pulmonary artery pressures. It is preferable to list patients before these treatment strategies are necessary. If patients are not listed at the time of diagnosis, then close follow-up with regular reassessment of the pulmonary artery pressure and resistance is necessary.

Dipchand et al. (99) reported that children with RCM were less likely to be listed as status 1, ventilated, or to be receiving inotropes, and had fewer arrhythmias at listing than their counterparts with dilated cardiomyopathy. However, their likelihood of death while waiting was similar, suggesting that these lower status patients were as vulnerable as the higher status children with dilated cardiomyopathy (99). Zangwill et al. (97) reviewed the outcomes of 145 children with RCM listed for heart transplantation, 44% of whom were listed UNOS status 1. They found that children requiring mechanical support and infants had a significantly higher risk of death while waiting than other children listed with RCM. These studies underscore the importance of not waiting "too long" to list these patients.

While listed for transplantation, patients should have periodic Holter monitoring performed, and as symptoms dictate, to evaluate for signs of ischemia, ventricular arrhythmias, or developing conduction disturbances. Implantable defibrillators should be considered for patients with evidence of ischemia and ventricular arrhythmias. Strenuous physical activity should be avoided.

Since the only definitive therapy for RCM, at the present time, is cardiac transplantation, better medical therapies are needed for the treatment of RCM. Improved methods of risk stratification are needed for RCM patients to identify those at greatest risk for thromboembolism, rapid progression of elevated pulmonary vascular resistance, and sudden death.

Muscular dystrophy (MD) is associated with cardiomyopathy (CM) (sometimes dilated), conduction disturbances, or both. Depending on the type of dystrophy, and possibly the location of the gene abnormality, expression can be variable. With the advent of genetic testing, these diseases are being studied much more systematically and vigorously. The result is that more specific information about each type and subtype has been gained. These newer understandings about the diseases and their nuances will ultimately lead to improved diagnosis and likely different classifications and therapeutic approaches.

MUSCULAR DYSTROPHIES WITH CLINICAL CARDIAC DISEASE

Myotonic muscular dystrophy is the most common form of MD (inclusive of both adults and children). On the basis of new molecular insights, at least two variants must be considered (1,2). The classic disorder is referred to as dystrophic myotonia type 1 (DM1). It is associated with a CTG repeat in the 3' untranslated region of dystrophica myotonica-protein kinase gene. Repeat size instability leads to anticipation in disease onset from one generation to the next, and the children of mothers with DM1 can have congenital dystrophica myotonia, a severe grave form of the disease in which the CTG repeat is far more expanded. In these infants, the cardiac manifestations are considerably more severe (dilated cardiomyopathy (DCM), cardiac rhythm disturbances, and sudden death). A second variant of myotonic dystrophy, characterized only in the last few years, is referred to as DM2. Several notable differences from the classic disorder start with the molecular defect characterized by a CCTG expansion in intron 1 of the finger protein 9 (ZNF9) gene. The cardiac manifestations also include conduction system disease as in DM1. The congenital form of the disease is not seen in DM2.

Dystrophin deficiency causes the second largest group of dystrophies with cardiac involvement (and the most common in childhood). The severity of the skeletal muscle disease correlates with the quality and quantity of dystrophin, the product of the X-linked *DMD* gene. *Duchenne muscular dystrophy* (DMD) is the most severe variant, and is typically associated with <5% of normal levels of dystrophin in skeletal muscle. *Becker muscular dystrophy* (BMD) is a milder form of dystrophinopathy, in which greater amounts of dystrophin protein are present in the muscle. These differences in dystrophin expression are due to differing *DMD* mutations that either truncate protein expression or allow expression of protein of diminished size or amount.

Another unique disorder with prominent cardiac manifestations is *Emery-Dreifuss muscular dystrophy* (EDMD).

EDMD refers to a syndrome caused by more than one gene defect. The classic disease, X-linked EDMD (XL-EDMD), is marked by striking contractures (particularly at the elbow) and in most cases is caused by a mutation of the *STA* gene that encodes emerin, a protein of the inner nuclear membrane. Recently, another X-linked gene *FHL1* has been demonstrated to be the cause of about 10% of XL-EDMD (3). Mutations in the *LMNA* gene are responsible for autosomal forms of EDMD, which occur most commonly as autosomal dominant (AD) and occasionally as autosomal recessive (AR) traits. Both are almost identical in signs and symptoms to the X-linked form. The *LMNA* gene encodes alternatively spliced isoforms of type A lamins, lamin A and lamin C (4). Lamins are found on the inner nuclear membrane where they interact directly with other proteins including emerin, seeming to account for the overlapping clinical picture. Perhaps adding to the confusion is a DCM occurring in the absence of MD also associated with LMNA mutations. On the other end of the spectrum, adding further complexity to the LMNA phenotypes, is a generalized form of weakness affecting pelvic and shoulder muscles referred to as limb-girdle muscular dystrophy 1B (LGMD1B). It is distinct clinically from EDMD because of lack of extremity contractures. Of particular relevance, LMNA mutations causing LGMD1B, EDMD, and DCM all carry a risk of atrial arrhythmia, CM with heart failure, and sudden death (probably owing to tachyarrhythmias (5).

The limb-girdle muscular dystrophies (LGMDs) are a clinically and genetically heterogeneous group of disorders. LGMDs include both AD (LGMD1) and AR (LGMD2) forms. Based on linkage analysis, letters of the alphabet have been sequentially assigned to these disorders depending on the order in which linkage was established. Thus far identified and classified are six types of LGMD1A to 1E and fourteen subtypes of LGMD2A to 2N (6). Patients usually have pelvic girdle weakness with varying degrees of shoulder girdle muscle weakness. Mild contractures are seen with LGMDs but are never the predominant clinical feature as seen in EDMDs. The LGMD phenotypes with CM are described later.

A comment about the term *X-linked cardiomyopathies* is necessary here for clarification. This is a clinical term that did have value in the premolecular genetic era, but, with our current degree of understanding regarding specific gene defects, it is best to consider the major X-linked cardiomyopathies separately. Four separate genetic disorders with cardiac and skeletal myopathies are found on the X chromosome. DMD and BMD already have been discussed. These disorders, caused by the same gene mutation with varying degrees of dystrophin deficiency, are linked to the short arm of the X chromosome at Xp21. The other major CM on the X chromosome, EDMD (7), with a mutation in the *STA* gene, is linked to the long arm of the X chromosome at Xq28. A third CM on the X chromosome

is Danon disease (8), also known as X-linked vacuolar CM and myopathy, which is caused by a mutation in the gene encoding lysosome-associated membrane protein-2 (*LAMP2*) at Xq24. This form of dystrophy can have hypertrophic CM. The final disorder of this group is Barth syndrome (9). It is perhaps the most novel of these X-linked disorders. It is a mitochondrial disease caused by a mutation of the tafazzin gene associated with decreased amounts and altered structure of cardiolipin, the main phospholipid of the inner mitochondrial membrane. The gene maps to the long arm of the X chromosome at Xq28. Patients have variable clinical findings, often including heart failure, CM, neutropenia, and growth retardation.

ASSESSMENT TOOLS

Electrocardiography

Since many of the dystrophies affect cardiac conduction, the electrocardiogram (ECG) offers important information regarding abnormalities of rhythm, rate, axis, and pattern change(s). Specific abnormalities are discussed below with respect to findings in particular lesions.

Holter Monitoring

Twenty-four-hour electrocardiography gives insight into arrhythmias and disorders of conduction seen in patients who are often asymptomatic. It also allows measurement of heart rate variability in patients with disordered automaticity.

Echo Doppler Studies

Somatic deformities associated with various forms of dystrophy may include chest wall deformities and kyphoscoliosis that distort the relationship of lungs and heart, creating challenges for ultrasound evaluation. It is important to record and measure the left ventricular dimensions in diastole and systole, areas of dyskinesis and akinesis, anterior mitral valve leaflet E-point septal separation (EPSS), shortening fraction (SF), ejection fraction (EF), and rates of wall contraction and relaxation. Planimetry of 2-D images allows fairly accurate predictions of left ventricular volumes and EF. More recently, the sphericity index, derived from comparing the long-axis left ventricular dimensions in diastole and systole with the chord from the mitral annulus to the apex in diastole and systole, has been used to quantify the myopathy. The value should be <0.66 . If it approaches 1.0, it indicates that the chamber is rounded instead of elliptical (remodeled), and a dilated myopathy is likely (10).

Friedberg and Silverman (11) have defined criteria for DCM that include prolonged systolic duration and shortened diastolic duration. Doppler mitral and tricuspid regurgitation jet durations were used to measure systole. Diastole was measured as the time from cessation of the regurgitation jet to the onset of the next atrioventricular (AV) valve regurgitant jet. A ratio of systolic time/diastolic time was derived and corrected in relation to heart rate. The tricuspid systolic interval/RR interval in normal subjects was 0.41 ± 0.07 (mitral, 0.42 ± 0.08), and the systolic/diastolic ratio in normal subjects was 0.77 ± 0.24 . There are few studies in MD that have used this method, but it holds promise as another useful measurement. See Chapter 9 for a detailed description of functional testing by echo and Doppler techniques.

Doppler analysis is used to demonstrate mitral and aortic valve regurgitation. Quantification of tricuspid regurgitation

allows prediction of systolic right ventricle and pulmonary artery pressures. Evaluation of pulmonary regurgitation allows estimation of pulmonary arterial diastolic pressures. It also is possible to estimate cardiac output by planimetry of the pulsed Doppler aortic waveforms with respect to space and time. Newer studies, especially in adult patients, and a few in the pediatric population, have used Doppler tissue analysis to evaluate wall contractile function and diastolic function. These approaches are beginning to have usefulness for evaluation of CM in the MD population.

Because many of these patients cannot exercise physically, dobutamine stress echo studies may provide information regarding myocardial performance, especially in patients with borderline normal resting studies. These studies should be performed carefully, recognizing that atrial and ventricular tachyarrhythmias could occur during such stress testing.

Other Imaging Methods

Other tools can be used to measure left ventricular volumes and derivation of EFs when patients cannot have adequate echo studies; these include magnetic resonance imaging (MRI), computerized tomography imaging, radionuclide imaging, and positron emission testing. Each has advantages and disadvantages, including cost, accessibility, and limitations, for example, the presence of metal rods in patients with previous scoliosis surgery may interfere with MRI analysis. There may be variability in the information that can be derived from these other imaging methods depending on the availability of the most recent equipment and the sophistication of the software used for analysis.

MUSCULAR DYSTROPHIES WITH CARDIAC INVOLVEMENT

Dystrophinopathies

DMD and BMD are related disorders (12–14), differing in severity because of the amount or quality of the expressed dystrophin protein. In nearly all cases, DMD patients express $<5\%$ dystrophin in skeletal muscle biopsies, an amount insufficient to maintain ambulation much beyond age 12. In contrast, in BMD, the gene mutation permits varying degrees of dystrophin expression that can be quantified on skeletal muscle biopsy. In most cases, both the quantity and the size of dystrophin are reduced. The amount of dystrophin expressed also can be determined by cardiac biopsy, but this is not a common or practical approach. It is important to understand that BMD covers a very broad spectrum of disability from mild to severe depending on the specific gene mutation. It also is important to note that skeletal and cardiac muscle may exhibit paradoxical clinical responses. In DMD with severe skeletal muscle loss early in the course of the disease related to almost complete dystrophin deficiency, patients lose ambulation between 10 and 12 years of age and have a sedentary wheelchair-dependent lifestyle. In this environment, there may be very little stress on the heart on a day-to-day basis. This probably accounts for the uncommon presence of symptoms and signs of clinical heart failure, which often do not manifest without a catastrophic event, such as a life-threatening pulmonary infection. In contrast, the patient with BMD who has CM will have more skeletal muscle and preserved ambulation that create more cardiac demands, leading to symptoms of heart failure that mandate treatment.

DYSTROPHINOPATHIES: DUCHENNE MUSCULAR DYSTROPHY

Boys with DMD have few problems in the neonatal period. Some have delayed onset in walking independently. They sometimes crawl later than average. The disease usually is not recognized until about 3 years of age because the affected boys run and jump poorly and cannot keep up with other children in normal play activity. If there is a known family history, for example, siblings with DMD, a new male infant may be recognized as having DMD with CK and genetic confirmation. Through such recognition, the Muscular Dystrophy Association is sponsoring a multicenter trial of early diagnosis and natural history in infants. By school age, the difference in muscular function becomes very apparent. Stair climbing usually requires a handrail. They usually climb stairs one step at a time rather than alternating from step to step. Falling becomes an increasing problem. Facial injuries can result from forward falls because the arms are too weak to brace against the fall. To get up from the floor, boys roll to a prone position, spread their legs for balance, first lift their buttocks and then “walk” their hands up their legs (Gower sign). By age 6 to 7 years, most boys assume a waddling gait with a lordotic posture. Walking becomes increasingly difficult about age 10, and without intervention, most of these patients will become wheelchair dependent by about age 12. For the DMD population at large, the IQ is reduced by approximately one standard deviation (SD) from the normal population. Cognitive difficulties affect verbal and memory skills selectively.

On physical examination, certain features are easily recognized and include the following: enlarged (hypertrophied, not “pseudohypertrophied”) calf muscles that feel rubbery on palpation; weak neck muscles that cannot raise the head from supine, especially if the neck is first hyperextended; and weakness of proximal muscles of varying degrees, always worse than distal muscle. Late in the course, all muscle function is impaired except for minimal hand movement. Diaphragm and intercostal muscles are compromised, leading to poor cough, aspiration, and predisposition to pneumonia. A typical scenario is an episode of pneumonia that increases cardiac demands leading to heart failure. Some patients may have a tachyarrhythmia at any time prior to this. Death has historically occurred sometime in the early twenties, although aggressive and early use of nocturnal ventilatory support may have created a significant impact in extending life expectancy (15).

Cardiac Pathology

Cardiac involvement is universal. There is epimyocardial muscle replacement with fat and fibrosis beginning in the left ventricular posterior wall behind the posterior mitral annulus. Histologic studies show that the fibrosis begins at the epicardium and progresses toward the endocardium (16). The myocardial scarring progresses apically and ultimately invades the septum (17). The right ventricle and the atria seldom are involved. The fibrosis leads to dysfunction and occasional dilation, especially with severe dysfunction, with initial thinning and even outpouching of the left ventricular posterior wall behind the mitral area to a severe generalized CM. It is possible that the left ventricle cannot dilate if the wall is severely fibrotic, creating a restrictive myopathy. If dilation is present, the patient can develop mitral regurgitation and occasionally, aortic regurgitation. With left ventricular failure, there can be secondary pulmonary hypertension and right ventricular failure associated with pulmonary and tricuspid regurgitation. Fibrosis and fatty infiltration also can involve the conduction system, including the sinoatrial (SA) node and AV node (18,19).

Cardiac History and Physical Examination

The patient has very few cardiac complaints, mainly because of physical inactivity. Even those with severe CM have few symptoms, other than shortness of breath, which can also be due to respiratory compromise from their weak chest and diaphragmatic musculature. Some will have postural nocturnal dyspnea. Others may detect palpitations if they have ventricular or atrial arrhythmias.

It is important to realize that patients with DMD and BMD can have severe complications from anesthesia, including cardiac arrest. Most complications seem to be related to use of succinylcholine, a muscular relaxant that may trigger hyperkalemia (20). Others have been attributed to use of volatile anesthetic agents. Patients also can have a reaction similar to malignant hyperthermia (20), develop rhabdomyolysis, and have masseter muscle spasm. It is apparent that anesthesia must be approached with caution in patients who have dystrophinopathies (20,21).

The cardiac examination is seldom abnormal, even in the presence of CM. Occasionally, third or fourth heart sounds may be present. According to Perloff et al. (22), a pulmonary outflow murmur is present in most patients, but that has not been our experience. Some will have a click and murmur of mitral valve prolapse; we have heard this in patients with severe chest wall deformities secondary to scoliosis. There may be neck vein distention, peripheral edema, or sacral edema. The overall examination is often distorted by chest wall deformities, especially in older patients who have scoliosis.

Electrocardiographic Features

Historically, we have been taught that the characteristic ECG in Duchenne shows a shortened PR interval, deep Q waves in leads I, aVL, V5, and V6, and occasionally in leads II, III, and aVF. There is often a tall right precordial R wave and an increased R/S ratio (19,23) (Fig. 58.1). Some have reported QT prolongation (24,25) and QT dispersion abnormalities (26).

A recent prospective study of 115 boys with DMD (40 with CM) confirmed that the most commonly seen findings were (a) short PR interval (43%), (b) Right Ventricular Hypertrophy (RVH) (37%), (c) prominent Q waves in leads V5 (34%) and V6 (33%), (d) Q waves in the inferior lateral leads in only 9, and (e) Q waves in leads I, aVL, V5 and V6 in only 3. None had prolonged QTc intervals, Two had ST-T depression (1 with CM) and 38 had flat/biphasic ST segments (15 with CM). The EKG did not discriminate the CM subgroup from the DMD boys who had EF > 55% (27).

An unpublished recent serial analysis of 154 DMD boys (91 with CM) studied prospectively over a 9.4-year period with a total of 805 EKGs (367 in CM group) showed no correlation of RVH amplitude with echocardiographic LVID, EPSS, SF, or EF. Thus RVH does not correlate with CM (Thrush PT, Allen HD, *unpublished data*).

Another recent retrospective study of 150 MD patients, including 86 DMD boys (51 with CM defined as EF < 55% or LVIDd > 2SD = 59%) showed that abnormalities (mainly repolarization artifacts, ST-T changes, RVH, or BVH) correlated well with a general MD population who had CM defined as left ventricular internal dimension at diastole (LVIDd) > 2 SD or EF < 55%. The DMD population was not separated in the retrospective paper's data analysis but abnormalities were seen in only 63/213 (29.5%) of the DMD EKGs that were analyzed. There was no mention of shortened PR interval or correlation with CM in the DMD subpopulation (28).

Holter analysis has shown that automaticity is also affected whereby there is a resting sinus tachycardia, loss of circadian rhythm, and reduced heart rate variability in many patients

FIGURE 58.1. ECG from a 20-year-old patient with DMD. Note the shortened PR interval; Q waves in II, III, aVF, V5, and V6; intraventricular conduction delay; and RVH. The QTc was 430 ms.

with DMD (29–33). There are frequent arrhythmias in older patients including ectopic atrial tachycardia, atrial fibrillation, transient second- and third-degree AV block, and more ominous ventricular tachycardias (Thrush PT, Allen HD, unpublished data) (29). One publication showed that there was a predictive ECG pattern in terminal DMD consisting of $RV1 < 0.6$ mV, $RV5 < 1.1$ mV, and $RV6 < 1.0$ mV; abnormal T waves in II, III, aVF, V5, and V6; conduction disturbances; ventricular premature contractions (VPCs); and sinus tachycardia (34). The presence of multiform VPCs and ventricular tachycardia on Holter monitoring portends possible sudden death due to ventricular fibrillation (35–37).

Doppler Echocardiogram and Other Imaging Studies

The echocardiographic findings in boys with Duchenne correlate with the autopsy findings of posterior epicardial thinning leading to ultimate DCM. The first descriptions were by Goldberg et al. (37), who showed thinner left ventricular posterior walls, especially behind the posterior mitral valve leaflet, diastolic dysfunction, contraction abnormalities that progressed inferiorly, and temporally progressive wall thinning in these patients during serial studies (37–40). Other serial studies showed progressive deterioration toward left ventricular dilation and dysfunction by evaluation of left ventricular diameter changes (25) (Fig. 58.2), systolic time interval changes (38–40), and development of mitral valve prolapse (35).

Findings of CM do not necessarily parallel the progressive skeletal muscle changes (41,42). Increasing left ventricular

FIGURE 58.2. M-Mode tracing from a 24-year-old patient with advanced DMD. His e-point septal separation was nearly 2 cm (normal is < 5 mm).

FIGURE 58.3. Two-dimensional long-axis echo from patient in Figure 61.2. Note the dilation of the left ventricle at 4.6 Z score (SDs). His EF on afterload reduction and beta-blocker treatment is 39%, and SF is 19%. The sphericity index is 0.8 (normal is <0.66). He has posterior wall thinning, and that area is nearly akinetic.

diastolic and ultimately systolic volumes, decreasing shortening and EFs, and increasing sphericity indices (10,43) (Fig. 58.3) indicate worsening CM (43–45). Tissue Doppler echocardiography studies have shown decreased systolic contraction and diastolic relaxation rates in patients with DMD, even when they had otherwise normal echocardiographic findings (44,45). Further studies using this technology are necessary to confirm these findings, but it appears to be promising for assessment of these populations.

FIGURE 58.4. MRI from same patient as in Figures 59.2 and 59.3 (Courtesy of Stephen Cook, MD.). **A:** Note that fibrosis (white appearance) posterior to the mitral papillaries has nearly completely replaced muscle. **B:** Fibrosis extends through the myocardium. Functional information was similar to the echo results.

One study using equilibrium radionuclide angiography in 9- to 18-year-old patients with DMD showed normal resting EFs (>50%) in 79% of the patients and normal right ventricular EFs (>45%) in 95%. However, when they used dobutamine perfusion, there were marked age-related decreases in both left and right ventricular EFs (46). Another 5-year follow-up serial radioisotope study showed resting changes in the septum that portended a fatal outcome (47).

MRI and angiography hold great promise for detection of scarring and fibrosis within the muscle (48–50) (Fig. 58.4) and quantification of left ventricular function by using circumferential strain analysis (48,51,52) (see chapter 10). The presence of non-steel-containing Harrington rods is not a contraindication for MRI evaluation. These studies have shown that fibrosis and abnormal circumferential strain are noted long before EF abnormalities are seen on echo. This raises the question of “what/when is CM in DMD?” Perhaps CM is always present in DMD regardless of age (Canter CE, *personal communication*, St. Louis Children’s Hospital, 2011).

Neuroendocrine Abnormalities

Plasma α -atrial natriuretic peptide (α -ANP) and brain natriuretic peptide (BNP) levels are elevated in adults with congestive heart failure. A few studies of patients with DMD have shown these to be elevated in patients with echocardiographic evidence of left ventricular dysfunction (EF \leq 15%) or end-stage cardiorespiratory failure (53,54). More studies are necessary to clarify the meaning of these findings, but ANP and BNP levels seem to be a promising method of evaluating these patients and assessing the patient’s response to treatment (see Chapter 73).

Therapy

The approaches to treatment include symptomatic, preventive, and curative. Most emphasis had been on treating symptoms, but they are seldom present in DMD boys. In the past, the empiric standard treatment was use of digitalis and diuretics. Digitalis has fallen out of favor with many cardiologists who treat DMD because of its proarrhythmic potential.

A recent consensus statement recommends doing echo exams after the age of 6 years and repeating them at least every 2 years thereafter until 10 years of age, then annually. "Use of standard heart failure interventions with deterioration of function"—"even if asymptomatic"—was also recommended (55).

More recently, afterload reduction with angiotensin-converting enzyme inhibitors (ACE inhibitors) has been used with some success (42). Some (42,46,47,56) have advocated using ACE inhibition for patients with EF <55%, left ventricular dilation (>2 Z scores/body surface area [bsa]), sphericity index (>0.66), and/or an abnormal tissue Doppler myocardial performance index (<0.35). They (42) reported that ACE inhibition (and sometimes additional beta-blocker treatment if the echocardiographic indices of remodeling did not improve after 3 months) resulted in stabilization in 2 of 29 boys, improvement in 8 of 29, and normalization in 19 of 29 (16 Duchenne, 3 Becker). Others have evaluated a similar population with EF <55% who were treated with ACE inhibition with varied results (56). Some controversy exists as is evident from a letter to the editor (57) responding to this study with many important questions about the true effect of the drug, selection bias, and variable expressions of the disease.

Viollet, Thrush et al. (58) evaluated the natural history and responses to treatment in a prospective study of 65 boys with DMD and CM. Natural history information was available on 24 patients before onset of CM. The expected downward trend was noted with mean EF decreasing from $53\% \pm 8.5\%$ to $44.3\% \pm 8.3\%$ over a mean 40-month period, ranging from 6 to 50 months. By Kaplan-Meier analysis, the mean age of onset of CM was 14.1 years, similar to that seen in other studies. The range in age of onset of CM was 7 to 27.3 years. ACE inhibitor (lisinopril) was initiated when the EF <55%. Beta-blocker therapy (metoprolol) was used to treat disordered automaticity (average 24-hour heart rate >100 bpm). The CM population separated into two groups, those receiving ACE inhibitor only (mean age 14.1 years), and those receiving ACE inhibitor plus β -blocker (mean age 16.1 years). The responses to treatment were similar ($p = 0.947$) between the two groups, with the ACE inhibitor group improving from mean EF 48% to 54% ($p < 0.0001$) and the ACE inhibitor + β -blocker group from mean EF 45% to 50% ($p < 0.001$).

ACE blocker (ARB) therapy has also been advocated with the argument that they are less prone to complications of cough and by inhibition of the TGF- β signaling and is associated with skeletal and cardiac muscle regeneration in the MDX mouse model of DMD and Marfan (59, 60). An muscular dystrophy association (MDA)-sponsored multicenter study prospectively evaluating ACE inhibitor versus ARB including skeletal muscle evaluations is presently under way to see if one treatment has advantages over the other.

Other investigators (61,62) used neuroendocrine parameters along with echocardiographic evaluation of left ventricular function to determine whether or not to treat. They defined left ventricular failure on the basis of an EF of <40%, fractional shortening of <20%, and left ventricular dimension >2 SD. Elevation of ANP and BNP correlated with echo findings, and many of the patients were symptomatic. After treatment with ACE inhibitor and beta-blocker, neuroendocrine levels normalized and echo parameters improved. Improvement was temporary for some of the patients who worsened after normalizing. Increasing neuroendocrine levels portended impending death. Clearly, ongoing prospective studies of whom to treat, which parameters should be used to indicate the need for treatment, serial assessment, and clear measurements of outcomes are necessary.

Ventricular tachyarrhythmias are ominous and warrant treatment with an appropriate agent. Often, a beta-blocker is the first drug used, followed by class III agents such as sotalol

or flecainide. An automatic implantable cardioverter defibrillator may be considered for this problem, as well as in patients with EFs <15%, similar to the approach used in adult patients with congestive heart failure.

Preventive treatment is a debatable topic. The usual adult patient with congestive failure is treated once the EF is <50%. What number should be applied to the Duchenne patient to imply the correct time to use an ACE inhibitor? Will it make any difference? The work of Jefferies et al. (42), Towbin et al. (45) implies that it might be beneficial. Again, serial controlled double-blind studies are necessary to answer these questions.

The timing of initiation of heart failure care is debatable and often is accomplished when there are obvious signs or symptoms of decreased cardiac function. However, a recent study in a mouse model of DMD noted a protective effect of early initiation of an aldosterone antagonist (Aldactone) in combination with an ACE inhibitor (lisinopril) on both skeletal and cardiac muscle (63). The mechanism is thought to be related to the antifibrotic effects of this class of medications in combination. Cardiac and skeletal muscle function evaluated *ex vivo* remained at 80% of normal with this therapeutic regimen whereas those mice not treated had a decline to 40% of normal (63).

Some have noted that eplerenone, another aldosterone antagonist that does not have the gynecomastia effects that are seen in teen boys taking Aldactone may be a valid substitute. An adult trial in patients with congestive heart failure showed reduced risk of death and fewer hospitalizations in the cohort studied (64). Additionally, the drug has been used safely in a pediatric population with systemic hypertension (65). A multicenter MDA-sponsored "prophylactic" trial will be under way in the near future to assess the effects of this drug on cardiac fibrosis and abnormal systolic strain evaluated by serial MRI in a DMD population.

As therapy initiation is debated, detection of early cardiac changes is also being evaluated further. Echocardiographic and cardiac MRI advancements have led to earlier detection of functional changes of the myocardium in many disease states. A recent study in those with DMD evaluated left ventricular myocardial peak circumferential strain via advanced cardiac MRI techniques and found that in patients with a normal EF, the peak circumferential strain was decreased and echo EF showed abnormality at a mean age of 15.8 years (49,50). Patients <10 years of age exhibited abnormal strain, and older boys had a further decline in strain analysis. It is thus hypothesized that using tissue Doppler and strain analysis on patients with DMD even with a normal EF may lead to early detection of myocardial changes (49). This study did not follow patients longitudinally, and therefore, no strong conclusions can be made as to the natural history of cardiac changes in those with DMD and to the applicability of a management scheme of early detection and therapeutic intervention.

In selected patients with end-stage heart failure where usual medical therapies have been optimized and symptoms persist, outpatient inotropic support has been reported (66). The use of milrinone at home is not without potential adverse events, and a detailed discussion with the family in regard to the role and risks of this therapy must be done prior to initiation. Inherent risks exist with long-term access including infection; however, inotropic support is associated with a multitude of potential side effects, yet potential exacerbation of arrhythmias is paramount. Nonetheless, inotropic support may allow for more time at home or school and may provide symptomatic relief (66).

Clinical trials have been done sporadically in this patient population to assess novel therapies. Recently, idebenone, a

benzoquinone with antioxidant properties, which improves respiratory chain function and cellular energy production, was evaluated in a double-blind, placebo-controlled trial in 21 patients with DMD ranging in age from 8 to 16 years (67). Idebenone was found to be safe and well tolerated and its use was associated with a trend toward an increase in strain of the left ventricular inferolateral wall. Additionally, from a respiratory standpoint, there was a significant increase in peak expiratory flow. It is felt that this drug may be suited for those with DMD due to its facilitation of electron flux along the mitochondrial respiratory chain and the reduction of oxidative stress (67). A larger trial is ongoing. Other current trials that are enrolling subjects include an evaluation of the effect of sildenafil on cardiac remodeling as well as another one studying carvedilol in a preventive fashion in those with DMD.

Duboc et al. (68), in a multicenter trial of an ACE inhibitor, perindopril, did a prospective double-blinded trial where 57 boys with DMD and normal EF (>55%) by radioisotope evaluation were in a 3-year evaluation where they received either ACE inhibitor or placebo, followed by 24 more months, when all received ACE inhibitor. Left ventricular ejection fraction was checked at baseline, 3 years, and 5 years. Although there was no significant difference between the treatment groups at 3 years or 5 years ($p = \text{ns}$), individually, one patient in the treatment group versus eight in the placebo group had EF<45% at the end of the trial ($p = 0.02$). A 10-year follow-up study (69) of members of the study groups showed that 26/28 patients in the treated group were alive versus 19/29 in the placebo group. Kaplan-Meier survival was significantly lower in the placebo group ($p = 0.13$). From this, he concluded that early (9.5 years of age) treatment with ACE inhibitor was associated with lower mortality. Although the causes of deaths were not detailed, the study is provocative and has resulted in many centers adopting a “prophylactic” approach by treating all boys with DMD, as Duboc suggests, with an ACE inhibitor after 9.5 years of age.

The obvious hope is that a cure for this genetic disease is on the horizon. A wide range of prospects exists, which include growth-modulating agents that increase muscle regeneration and delay fibrosis, antisense oligonucleotides (2'-O-methyl phosphorothioate backbone or morpholinos) with the capacity to skip exons and agents designed to suppress or stop codon mutations, gene-therapy approaches including strategies to replace or repair genes or use surrogate genes to replace defective ones, and stem cell therapy, especially using mesangioblasts. What effect will any of these approaches have on the myocardium? Future studies should help answer this question. If these treatments do not improve the myocardium, it is incumbent upon the pediatric cardiology community to evaluate and employ the most effective cardiac therapies possible so that the hopes for skeletal muscle improvements are not encumbered by congestive heart failure.

Another question is whether we should reevaluate our therapeutic attitudes toward this population in light of improved pulmonary care, greater longevity, and possible improvements in skeletal muscle from gene therapy or exon-skipping treatments. If severe heart failure happens at a young age, what is the role of synchronization pacing, ICDs, or destination treatment, either mechanical (see Chapter 21) or transplant (see Chapter 65)?

The Duchenne Carrier

Few investigators have evaluated DNA-proven Duchenne and Becker female carriers (mothers and sisters). Earlier evaluations showed ECG abnormalities (70,71). Hoogerwaard et al. (72) studied 129 female Duchenne ($n = 85$) and Becker

($n = 44$) carriers and found that 47% had ECG changes (50% Duchenne, 40.9% Becker) similar to those seen in the dystrophinopathy patients. DCM detected by echo was present in seven Duchenne carriers (one was symptomatic) and in none of the Becker carriers. Subtle echocardiographic findings were present in 36% of the entire group (38% Duchenne, 34% Becker). Only 38% had normal echoes and ECGs. A more recent study (73) showed that DMD carriers (heterozygotic mothers) had mildly lower EF at rest versus controls (EF 55% vs. 62%) and after exercise, mean EF fell to 53% versus 73% in controls. Twenty-one of the twenty-four had one or more of abnormal resting EF, EF response to exercise or exercise-induced LV wall abnormality. These studies imply the need for evaluation of proven female carriers, even if they are asymptomatic.

DYSTROPHINOPATHIES: BECKER MUSCULAR DYSTROPHY

By strict criteria, patients with BMD remain ambulatory until 15 years of age and older. This is an arbitrary cutoff between DMD and BMD because the disorders represent a continuous spectrum related to the quantity and quality of dystrophin. In most cases, dystrophin is reduced in amount and size (74,75). In addition, the clinical disease varies from very mild to very severe, meaning that patients may lose ambulation shortly after age 15 years or remain ambulatory for many decades (62). Serum creatine kinase (CK) levels are very high, falling into the same range as the patients with DMD (usually >20 to 75 times normal). Again, the cardiac manifestations do not necessarily correlate with skeletal muscle progression and can be present sooner or later than the skeletal problems (75,76).

The ECG findings in patients with BMD are similar to those in patients with DMD with prominent Q waves in I, aVL, and V6, or in II, III, and aVF; tall R waves in V1; and increased QT dispersion (70). They can have supraventricular arrhythmias including atrial fibrillation/flutter and can have ventricular arrhythmias, especially toward end-stage myocardial dysfunction (77,78–80). They can also have ST changes and prolonged QTc intervals but do not have the problems with automaticity that patients with DMD show (31,32).

Their cardiac involvement is that of a DCM, sometimes starting with right ventricular dilation (80,81) and progressing to a generalized DCM. The presence of cardiac involvement with BMD is associated with exon 49 deletion and in most with exon 48 deletion according to a study by Melacini et al. (80), although other studies have not confirmed this observation, including a later study from the same group (82,83). Additionally, a recent MRI study showed many of the same findings seen in DMD, including fibrosis and was more discreet in detecting abnormalities of EF than echo (84).

A much more extensive analysis of genotype–phenotype correlation in BMD patients addressed age of CM onset and the protein domain deleted, showing that early-onset CM was associated with mutations in the amino-terminal domain; in contrast, deletions removing portions of the rod domain along with the hinge 3 domain have a later onset, likely due to preservation of the spectrin-repeat structure of the protein (85).

One study of 13 patients with BMD with cardiac involvement (78) showed that only one was wheelchair dependent. Since skeletal muscle is better preserved in BMD than in DMD, cardiac transplantation is a therapeutic option that can be lifesaving for patients with BMD assuming that they

have first had a careful trial of medical therapy, including use of afterload-reducing agents and, in some, implantable cardiac defibrillators (86–88). Use of mechanical support devices while awaiting transplant is desirable if necessary (see Chapter 21).

Multidisciplinary care of patients with DMD and BMD may enhance quality of life and life expectancy. In addition to neurologic and cardiac sequelae, respiratory failure from muscle weakness is a prominent issue with these patients. Some data advocate early intervention with noninvasive positive-pressure ventilation at the first signs of nocturnal hypoventilation. Positive-pressure ventilation physiologically reduces left ventricular afterload and is used for symptomatic respiratory relief of congestive heart failure in adults and adolescents. Noninvasive positive-pressure ventilation, even for periods of time acutely, may induce favorable hemodynamic effects on the left ventricle. However, theoretically, this intervention may elicit long-term improved hemodynamics (89).

DYSTROPHINOPATHIES: X-LINKED CARDIOMYOPATHY

Boys with this abnormality of the dystrophin gene complain of muscle fatigue, pain, and cramping with exercise but do not manifest the weakness seen in patients with BMD and DMD (90). Towbin et al. (91) analyzed one family and found a missense mutation at exon 9 of the dystrophin gene. They can have calf hypertrophy and have elevated serum CK levels (81). Some have no skeletal muscle dystrophin abnormality but have abnormalities of the cardiac dystrophin (14,91–93). Other studies have shown a mild decrease in skeletal muscle dystrophin with normal distribution, but no dystrophin was found in heart muscle (94). By the late teen years to early adulthood, they can develop a congestive CM that usually progresses to death within 2 years of the onset of the myopathy diagnosis. They also can have arrhythmias and AV block with much greater frequency than that seen in patients with either DMD or BMD. Of note, female carriers can show heart failure that is slowly progressive and often fatal (95).

MYOTONIC MUSCULAR DYSTROPHY

Myotonic MD, with its two adult forms (see above), DM1 and DM2, is inherited as an AD disorder representing the most common form of MD in adults (96). Patients may complain of sleep disturbances and gastrointestinal problems, both constipation and diarrhea, before developing muscle weakness. Progressive facial muscle, temporalis, sternocleidomastoid, and limb weaknesses develop along with cataracts (77). The weakness is unique among the common muscular dystrophies, affecting distal equal to or greater than proximal muscles. Patients also can have frontal baldness, diabetes, and frequently, infertility (97). When Steinert (98) described the disease, he noted that patients often had a slow pulse rate. Few adult patients have DCM, and pathology studies seldom show myocardial involvement (99). Conduction problems are common. They include bradycardia, prolonged PR interval, AV block, prolonged QRS and QT intervals, *torsades de pointes*, ventricular tachycardia and fibrillation, and atrial fibrillation/flutter with slow ventricular response owing to impaired AV conduction (93,100–102). These findings worsen with time and will be found in 75% of patients

with myotonic dystrophy (13,96,100,103). Cardiac syncope and sudden death have been reported, indicating that these patients would have benefited from pacemaker implantation (96). A recent study using MRI found that patients with fatty infiltration of the right ventricle correlated with the presence of inducible ventricular tachyarrhythmias in patients with myotonic dystrophy (101).

Affected children of mothers with DM1 show earlier and more aggressive expression of the abnormalities than seen in their mothers and in previous generations (anticipation phenomenon). Additionally, they often will present in infancy with an aggressive form of DCM (13,100–102).

EMERY-DREIFUSS MUSCULAR DYSTROPHY

In 1966, Emery and Dreifuss (7,104) described an X-linked MD that had unique clinical features including elbow, Achilles tendon, and posterior cervical muscle contractures that appear before muscular humeroperoneal weakness, including progressive biceps, triceps, anterior tibial, and peroneal muscle wasting with later pectoral, knee, and hip extensor weakness and ultimate development of complete heart block. In addition to the original X-linked form, another X-linked form is due to mutations in the *FHL1* gene, and autosomal forms of Emery-Dreifuss disease have been found to be dominant and recessive lamin A/C (*LMNA*) gene abnormality (5,105–111). (See introductory comments).

The progressive fibrous and fatty depositions mainly involve the atria, ultimately causing mechanical and electrical atrial paralysis. Patients can have prolonged PR interval, atrial fibrillation/flutter, bradyarrhythmia and tachyarrhythmia, stroke from atrial emboli, and death. Some patients will have late ventricular dilation, severe congestive failure, and arrhythmias. Pacemaker implantation can be lifesaving, but late deaths have happened even in patients who have pacemakers (7,105–115). Cardiac transplantation is sometimes lifesaving.

FACIOSCAPULOHUMERAL MUSCULAR DYSTROPHY

This disorder represents one of the most common forms of MD. It is inherited as an AD disorder that maps to chromosome 4q35, and is associated with an integral deletion in the number of a 3.3 kilobase (kb) repeat element, the D4Z4 repeat. This feature has for years allowed reliable diagnostic testing, but only recently has a unifying model of pathogenesis been proposed in which the deleted repeat results in a structural change at the D4Z4 locus, allowing the expression of the polyadenylated transcripts of the *DUX4* gene (116). *DUX4* encodes a transcription factor, and there is significant effort under way to understand the downstream targets that presumably play a central role in disease pathogenesis.

Clinically, patients have weakness involving face, scapular stabilizer muscles, and distal lower-extremity muscles. Progressive weakness involves both distal and hip-girdle muscles. The distribution of weakness is typically asymmetric. The disease is variable in severity with about 20% of patients being wheelchair dependent sometime in the course of the illness. Cardiac involvement has been reported in genetically confirmed facioscapulohumeral MD, but it is extremely rare, consisting of atrial and ventricular conduction defects (115).

LIMB-GIRDLE MUSCULAR DYSTROPHIES

LGMDs represent a group of disorders that share, as a common feature, weakness of the shoulder and pelvic girdles with onset around the second decade of life, and progression to significant disability over 20 to 30 years. Several genetic causes exist. So far described are six (LGMD1A to E) AD and fourteen (LGMD2A to N) AR types. A subset of recessive forms is caused by sarcoglycan deficiency (four isoforms include alpha [LGMD2D], beta [LGMD2E], gamma [LGMD2F], and delta [LGMD2]). Nonspecific CM and DCM rarely have been reported to occur in association with sarcoglycan deficiencies (seen in Amish families in Indiana) (77,116–119). Among the common forms of LGMD, only in LGMD2I (due to mutations in the *FKRP* gene, encoding fukutin-related protein) is CM frequently seen; altered EF may be detected in up to 60% of patients (120), and a case presenting with isolated DCM has been reported (120). Some patients with LGMD1B have had progressive AV conduction disturbances requiring pacemaker placement (121, 122).

Kawasaki Disease (Mucocutaneous Lymph Node Syndrome)

Sarah D. De Ferranti ■ Jane W. Newburger

Kawasaki disease (KD), first described in Japan in 1967 by Kawasaki, is now encountered worldwide (1,2). The first US cases were reported from Hawaii in 1976 by Melish et al. (3). Despite intensive research, the cause of KD remains unknown. The principal symptoms and associated features of the acute phase of the syndrome are shown in Tables 59.1 and 59.2. Although the cardiovascular manifestations of KD were not appreciated originally, by the mid-1970s, researchers reported that about 2% of affected children died suddenly in the subacute or convalescent stage of this illness due to myocardial infarction caused by acute thrombosis within coronary artery aneurysms or rarely from aneurysm rupture. Despite recent increases in incidence, current estimates of mortality in the United States are lower (0% to 0.17%) than originally reported (2), likely due to a combination of improvements in treatment and ascertainment of milder cases.

EPIDEMIOLOGIC FEATURES

While rare, KD is an important cause of acquired cardiovascular disease in the young that appears to be increasing in incidence. In Japan, nationwide biennial active surveillance shows the incidence of KD in children under 5 years of age has gradually increased from 74 per 100,000 in 1987 to 140 per 100,000 in 2000, and to 219 in 2008 (4,5). In children younger than 5 years of age, US estimates based on 2006 hospital discharge data suggest the annual incidence is 20 per 100,000 children (6). The typical KD patient is more likely to be male (ratio of males to females 1.5:1) and < 5 years of age (80%). In US children under 5 years of age, the prevalence of KD is the highest in Asians and Pacific Islanders (32.5 per 100,000), intermediate in non-Hispanic Blacks (16.9 per 100,000) and Hispanics (11.1 per 100,000), and lowest in Whites (9.1 per 100,000) (6,7).

Coronary aneurysms are the most important complication of KD. Young infants have the highest rate of coronary artery aneurysm formation and often present with incomplete clinical criteria. Children older than age 8 years also have a higher rate of coronary involvement (8–10). The rates of coronary artery aneurysm according to race/ethnicity have been estimated using administrative data; rates were highest in Hispanics (5.9%), followed by white non-Hispanics (3.4%), with blacks having lower rates (1.8%) (11). The study design did not allow the authors to determine whether differences in rates of aneurysms among racial/ethnic groups were related to late or inadequate treatment versus higher relative risk.

Children who have had KD once are at increased risk for a second episode. In Japan, the recurrence rate of KD is approximately 3%, and the proportion of cases with a positive family history is approximately 1% (12,13). Siblings have a relative risk that is 10-fold of the normal Japanese population; half

develop KD within 10 days of the first case (14). The risk of occurrence in twins may be as much as 100-fold higher than in the general population (14,15). These data, together with the occurrence of KD in the children of parents who themselves were affected, support the role of genetic factors in susceptibility to KD (12,14–16). Of note, in the United States, the familial incidence of KD appears to be much lower than in Japan.

ETIOLOGY AND PATHOGENESIS

An etiologic agent for KD has not been identified, despite extensive research into infectious, immunologic, and genetic causes. An infectious trigger is suggested by the epidemiologic characteristics of this syndrome, especially its tendency to target young children, time/place clustering, a predilection for winter and spring months, and epidemic cycles every 3 years (observed most clearly during the 1970s and 1980s). Indeed, various infectious agents have been proposed including rickettsia (17), propionibacterium (18), streptococci or their products (19), house dust mite antigen (20), and retrovirus (21). However, causality by these agents has not been independently confirmed. The clinical features of KD are similar to those of toxin-related diseases, such as scarlet fever or toxic shock syndrome, and to adenovirus. Furthermore, other processes can mimic the presentation of KD, such as drug reactions (Table 59.3). Exposure to recently shampooed carpets has been linked with KD in case-control studies, but additional studies contradict the association (22,23).

Immunologic causes of KD are another line of etiologic investigation. Vasculitides involve excessive or abnormal immune responses, and many hypothesize that, in KD, an infectious episode sparks a detrimental immune response in a host who is genetically or otherwise vulnerable. The suspicion of an immunoregulatory abnormality is supported by the activation of monocytes, macrophages, CD4+ T-helper cells, and B lymphocytes during the acute phase of illness (24). There is increased production of immunoglobulins, including circulating antiendothelial antibodies (25). In particular, IgA seems to be implicated; IgA plasma cells were found in the vascular wall and an oligoclonal proliferation of IgA was seen in several fatal KD cases (26). In addition to circulating immunoglobulins, cytokines are up-regulated, including interleukin (IL)-1, IL-2, IL-6, and tumor necrosis factor α (TNF- α) (24). Proinflammatory cytokines appear to render the vascular endothelium susceptible to lysis by antibodies (27). An example of this is the inflammatory mediator S100A12, which is involved in binding of advanced glycation end products (RAGE). Some studies report high RAGE levels that persist in patients who do not respond to intravenous immunoglobulin (IVIG) (28,29). Activated vascular endothelium expresses inflammatory antigens such as intercellular adhesion molecules.

TABLE 59.1 Principal Symptoms in Kawasaki Disease

Fever of at least 5 days' duration
Presence of at least four ^a of the following principal features:
Changes in the extremities, including erythema and/or indurative edema and later (2nd week of illness) membranous desquamation starting in the subungual regions
Polymorphous exanthema (but not including bullous or vesicular lesions)
Bilateral nonexudative conjunctival injection
Changes in lips and oral cavity (but not including discrete oral lesions)
Cervical lymphadenopathy, usually unilateral and large (≥ 1.5 cm)
Exclusion of other diseases with similar findings

^aPatients with fever and fewer than four principal clinical features can be diagnosed as having Kawasaki disease when coronary artery disease is detected by 2-D echocardiography or coronary angiography.

From Newburger JW, Takahashi M, Gerber MA, et al. Diagnosis, treatment, and long-term management of Kawasaki disease: A statement for health professionals from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Circulation* 2004;110:2747–2771, with permission.

Various mitogenic factors such as vascular endothelial growth factor and platelet-derived growth factors are expressed during acute and subacute phases. There is an extensive literature on markers of inflammation in KD, which generally rise more dramatically in patients with persistent fever or aneurysms. However, to date, there is no “diagnostic signature” of

TABLE 59.2 Features Associated with Kawasaki Disease

Clinical findings
Myocarditis
Pericarditis
Aseptic meningitis
Diarrhea
Gallbladder hydrops
Obstructive jaundice
Uveitis
Urethritis
Laboratory findings
Elevated acute phase reactants: CRP, sedimentation rate, α -1 antitrypsin
Thrombocytosis (usually in the 2nd and 3rd weeks of illness)
Sterile pyuria and proteinuria
Elevation of liver enzymes
Decreased serum protein and albumin
Anemia (normochromic, normocytic, and self-limited)
Negative or low antistreptolysin O titer

TABLE 59.3 Diseases and Disorders with Clinical Findings Similar to Kawasaki Disease

Viral infections (e.g., measles, adenovirus, enterovirus, Epstein-Barr virus)
Scarlet fever
Staphylococcal scalded skin syndrome
Toxic shock syndrome
Bacterial cervical lymphadenitis
Drug hypersensitivity reactions
Stevens-Johnson syndrome
Juvenile rheumatoid arthritis
Rocky Mountain spotted fever
Leptospirosis
Mercury hypersensitivity reaction (acrodynia)

From Newburger JW, Takahashi M, Gerber MA, et al. Diagnosis, treatment, and long-term management of Kawasaki disease: A statement for health professionals from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Circulation* 2004;110:2747–2771, with permission.

inflammatory markers that permits the reliable distinction of KD from other inflammatory processes.

If the pathophysiology of KD involves inciting infectious agent(s) that spark an abnormal immune response, the species responsible remain unclear. Various strains of *Staphylococcus* and *Streptococcus* have been proposed as the inciting immune perturbation, with toxins acting as superantigens recruiting T lymphocytes bearing V β 2 and V β 8 receptors (30). However, this hypothesis remains unconfirmed; in a prospective, multicenter study, the prevalence of toxin-producing strains was similar in patients with KD and febrile controls (31). Rowley et al. (26) identified immunoglobulin (Ig) A-secreting plasma cells within cardiovascular tissues from a number of patients who died from KD, suggesting that an unknown pathogen might have gained entry through the respiratory or gastrointestinal tract. The same investigators demonstrated immunohistochemical evidence of antigens within the respiratory epithelium and macrophages that react with synthetic IgA antibodies genetically engineered from these plasma cells (32).

A genetic predisposition of the host appears to be important in the pathogenesis of KD. This hypothesis is supported by the racial/ethnic differences in incidence (Asian and Pacific Islanders being more frequently affected) and the increased susceptibility of family members to KD (33). An increasing literature has explored the association of gene polymorphisms to susceptibility to KD or to development of aneurysms in those with KD (16,34–43), and studies are ongoing to examine this question. For example, patients with KD are more likely to have certain polymorphisms of the angiotensin-1 converting enzyme, the chemokine receptor CCR5 and ligand CCL3L1 (44), the butyrophilin-like 2 gene involved in T-cell stimulation (45), and inositol 1,4,5-trisphosphate 3-kinase C (ITPKC) SNP, the presence of which allows the T-cell response to be greater than the wild-type allele (46). A genome-wide association study implicated ATP-binding cassette, subfamily C (47), although this has not been confirmed elsewhere. Polymorphisms of endothelial growth factor and growth factor receptor and matrix metalloproteinase are associated with a greater

likelihood of coronary aneurysm formation in patients who have KD (40,48).

PATHOLOGY

Our understanding of the stages of cardiovascular pathology is based on the analysis of available postmortem specimens by Fujiwara and Hamashima (49) (Table 59.4). The initial 10 days of illness is characterized by a generalized microvasculitis. Clinical evidence of myocarditis may be present in the acute phase, and can persist into the first 3 to 4 weeks; right ventricular biopsies show mononuclear cell infiltration and edema within the myocardium and conduction system and late myocyte hypertrophy and fibrosis (50,51). Valvulitis may affect the mitral and aortic valves (52). Inflammation persists in the walls of medium and large arteries as a panarteritis, with particular predilection for the coronary arteries, and is characterized by edema, mononuclear cell infiltration, and progressive fibrosis with disruptions in the internal elastic lamina. Such destructive changes lead to aneurysm formation and are most common in the proximal segments and branching points of the coronary arteries, suggesting a role for hemodynamic stress in development of aneurysms (53). Aneurysms may be fusiform, saccular, cylindrical, or segmented (resembling beads on a string) (54,55). Noncoronary arteries, such as

iliac, femoral, axillary, and renal, are less frequently involved, and only in patients with coronary aneurysms. Involvement of intracranial arteries or intraparenchymal vessels within abdominal organs is extremely rare.

MANIFESTATIONS

Clinical Features: Systemic

The acute phase of KD often is preceded by prodromal upper respiratory or gastrointestinal symptoms (56). The beginning of KD is marked by an abrupt onset of high fever, accompanied by skin rash, conjunctival injection, reddening and fissuring of lips, erythema of the buccal mucosa, strawberry tongue, nonsuppurative cervical lymphadenitis, and erythema and edema of the hands and feet (1). The skin rash may take different forms, but bullae and vesicles are rare. The rash frequently begins in the diaper area and spreads to the torso and extremities. It may be evanescent, especially in young infants (see Table 59.1). Erythema and edema of the hands and feet may be accompanied by fusiform swelling of the proximal interphalangeal joints of the hands. Patients may refuse to move their hands or bear weight on their feet. Occasionally, they may show transient Raynaud phenomenon. The most dramatic extremity symptom is gangrene of fingers and toes, which occurs rarely in very young infants, mostly of non-Asian background (57). Clinical and spinal fluid findings of aseptic meningitis may be present in the acute phase.

This acute phase is followed by a subacute phase, which occurs from the 2nd to the 4th week of illness. During this time, most patients show desquamation starting in the subungual regions and spreading to the palms and soles. In addition to the principal symptoms, there may be hepatomegaly, hydrops of the gallbladder (58), transient jaundice, and abnormal liver function tests. Some patients develop transient diarrhea and abdominal discomfort. In some patients, arthralgia or arthritis appears late in the acute or subacute phase and very rarely may last up to 4 months (3). In the genitourinary system, the patient may show signs of urethritis and phimosis (in uncircumcised males) sometimes accompanied by dysuria and sterile pyuria. Orchitis may occur in boys. Transient and isolated peripheral nerve impairment such as facial palsy, phrenic nerve paralysis, or sensorineural hearing loss has also been described (59,60). Associated clinical and laboratory findings are summarized in Table 59.2.

If the patient remains untreated or is treated with aspirin only, the febrile course usually lasts from 1 to 3 weeks. The patient may show transient anemia and leukocytosis with increased numbers of neutrophils and bands. The platelet count increases in the 2nd and 3rd weeks of illness. Thrombocytosis and elevated sedimentation rate or C-reactive protein (CRP) will gradually subside by the 6th to 8th week of illness.

In Japan, KD recurs in 3% of the patients who have recovered completely from the original episode, although recurrent cases are less common in the United States. Children who have recurrent disease appear to be at increased risk of coronary complications (13). Recurrence of KD must be distinguished from so-called recrudescence, which is a variation within the acute phase of illness characterized by temporary remission of fever and other symptoms followed by relapsing fever. In the current era, recrudescence most commonly occurs after an initial response to IVIG therapy. Children with recrudescence fever, similar to those with recurrent disease, are at higher risk of coronary artery complications. It is important to instruct the family to monitor the patient's temperature daily after hospital discharge until the patient has been afebrile for a week, so that IVIG retreatment can be instituted if fever recurs.

TABLE 59.4

Stages of Cardiovascular Pathology in Kawasaki Disease

Stage 1 (0–9 d)

Microvascular angiitis

Acute endoarteritis and perivasculitis of major coronary arteries

Pericarditis, valvulitis, and endocarditis

Myocarditis including atrioventricular conduction system

Causes of death: heart failure and dysrhythmia

Stage 2 (12–25 d)

Panvasculitis of major coronary arteries with aneurysms and thrombus formation

Intimal proliferation of coronary arteries

Myocarditis, endocarditis, and pericarditis

Causes of death: same as in stage 1; also myocardial infarction, aneurysm rupture

Stage 3 (28–31 d)

Granulation of coronary arteries

Marked intimal thickening

Disappearance of microvascular angiitis

Cause of death: myocardial infarction

Stage 4 (40 d to 4 y)

Scarring, stenosis, calcification, and recanalization of major coronary arteries

Fibrosis of myocardium and endocardium

Cause of death: myocardial infarction

Summarized from Fujiwara H, Hamashima Y. Pathology of the heart in Kawasaki disease. *Pediatrics* 1978;61:100, with permission.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The 2004 American Heart Association (AHA) epidemiologic case definition of KD requires the presence of ≥ 4 days of fever and at least four of the five principal clinical features, including bilateral nonexudative conjunctivitis, erythema of the lips and oral mucosa, changes in the extremities, rash, and cervical lymphadenopathy (see Table 59.1) (61). When coronary artery disease is documented, the diagnosis of KD can be made with fewer than four principal features. All clinical features are rarely present at the same time, so the diagnosis requires sequential evaluation of the patient with detailed day-by-day history of the present illness.

No specific diagnostic test exists for KD, and many illnesses mimic KD (see Table 59.3: viral or rickettsial exanthems [measles, Epstein-Barr virus infection, and Rocky Mountain spotted fever], scarlet fever, leptospirosis, toxic shock syndrome, juvenile rheumatoid arthritis, Stevens-Johnson syndrome, reaction to drugs, and hypersensitivity to mercury) (62). Careful history, physical examination, and appropriate laboratory tests are necessary to exclude these conditions. At least moderate elevation of acute phase reactants, that is, the erythrocyte sedimentation rate (ESR) or CRP, is almost universal at the time of presentation. Both ESR and CRP should be measured because these test values may be discrepant at presentation (63). Elevations of liver function tests, including plasma gamma-glutamyl transpeptidase, transaminases, and bilirubin, are also common (62,64). Albumin synthesis declines in the acute phase, and hypoalbuminemia is common. Urinalysis shows so-called sterile pyuria, with white cells (often in the range of 10 to 50/high-power field [HPF]) noted on microscopic evaluation but not by dipstick. Lumbar puncture may show findings compatible with aseptic meningitis, with a predominance of mononuclear cells, but with normal glucose and protein levels (65). The degree of elevation of serum cardiac troponins in acute KD is controversial (66–68).

Although most cases fulfill the principal diagnostic criteria listed in Table 59.1, about 15% of cases have incomplete clinical presentations with coronary artery complications (69). In any child with unexplained fever lasting >5 to 7 days with some of the above-mentioned laboratory findings, the diagnosis of incomplete KD should be considered and echocardiography should be obtained (see section below and Fig. 59.3). Very young infants are especially likely to present with incomplete KD; indeed, some have fever as their only manifestation. For this reason, echocardiography should be performed on any infant younger than age 6 months with fever duration of ≥ 7 days, elevation of CRP and/or ESR, and no other explanation for the febrile illness.

ALGORITHM FOR CLINICAL EVALUATION AND TREATMENT OF CHILDREN WITH SUSPECTED KAWASAKI DISEASE

When the epidemiologic case definition for KD was first constructed by a committee of the Japanese Ministry of Health in 1970, the association of coronary artery sequelae with KD was not appreciated (70). Indeed, at that time, neither an effective treatment nor a noninvasive method of assessing coronary artery abnormalities was available. The original case definition was designed to be highly specific (i.e., to yield a low false-positive rate), but its sensitivity was limited and did not include echocardiographic data as part of the diagnostic criteria. Because coronary artery aneurysms are now well recognized to occur not only in children with typical KD but also in children with incomplete features of KD, and because IVIG therapy

must be given within the time frame of 7 to 10 days to be most effective in preventing coronary artery aneurysms, an algorithm for evaluation and treatment of the child with suspected KD was developed by members of the American Heart Association Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease that incorporates echo findings and laboratory tests (Fig. 59.1) (61). This algorithm as originally published was not evidence based, but rather reflected the consensus of experts. Salient features of patients with incomplete KD include laboratory tests indicating inflammation (e.g., elevated ESR, CRP, and white blood cell count), evidence of anemia, elevated alanine aminotransferase (ALT) and low albumin, and sterile pyuria. Ectasia and/or lack of tapering of the coronary arteries, left ventricular dysfunction, and, definitively, aneurysms support the diagnosis of KD in the incomplete presentation. The performance of the 2004 AHA recommendations for treatment of suspected or definite KD has been evaluated retrospectively in patients with definite coronary artery aneurysms. Of those with aneurysms, 97% would have received IVIG therapy with application of the classic criteria together with the algorithm for suspected incomplete KD (71).

Clinical Features: Cardiovascular

During the acute phase, patients may manifest signs of myocarditis, such as sinus tachycardia out of proportion to the fever, gallop rhythm, and sometimes muffled heart tones. These findings are generally self-limited and improve with IVIG treatment, although overt heart failure may occur occasionally. A pericardial effusion by echocardiography is not uncommon, but the effusions generally measure <1 mm (72); pericardial tamponade is very rare (73). Systolic murmurs are often heard owing to increased cardiac output and anemia, and approximately one-quarter of patients have mitral insufficiency (72). Rarely, children may present in low cardiac output shock.

Echocardiography may show mild diffuse coronary artery dilation and enhanced perivascular brightness in 30% to 50% of patients during the acute phase of KD. Without IVIG treatment, these lesions may become aneurysmal 1 to 3 weeks from onset of illness (average 10 days) (Fig. 59.2). The reported rates of aneurysm vary based on the definition of an aneurysm used. The Japanese National Kawasaki Disease surveillance data estimates the incidence of coronary aneurysms to be between 10.0% and 17.9%, with reported rates increasing as coronary dimensions are indexed to body surface area (BSA) (74). Information from the Pediatric Health Information System, an administrative database of free-standing children's hospitals, indicates lower rates of aneurysms at 1.8% to 5.9% (11). Coronary artery aneurysms tend to develop most frequently in the proximal segments of the left anterior descending and the right coronary artery (RCA), and less commonly in the left main coronary artery. The left circumflex branch is least often involved. An aneurysm in the distal arterial segment is usually but not always accompanied by an aneurysm in the proximal segment of the same artery. Aneurysms with internal diameters >8 mm or a z-score of ≥ 10 (so-called giant aneurysms) present disproportionately higher risks of myocardial infarction as compared with aneurysms of smaller dimensions (75,76). Several risk scores have been formulated to predict the development of coronary artery aneurysms based on clinical and laboratory data at presentation (77–81). Independent predictors include protracted fever, presumably reflecting worse vasculitis, anemia, elevated white blood count, low albumin, elevated CRP, male gender, and age younger than 1 year or older than 9 years. Younger age in particular seems to be an important predictor for worse presentation.

Evaluation of Suspected Incomplete Kawasaki Disease (KD)¹

Figure 59.1. This algorithm is a guide to evaluation of patients with suspected incomplete Kawasaki disease (KD). (1) In the absence of gold standard for diagnosis, this algorithm cannot be evidence based, but rather, represents the informed opinion of the expert committee. Consultation with an expert should be sought any time assistance is needed. (2) Infants ≤ 6 months old on day ≥ 7 of fever without other explanation should undergo laboratory testing, and if evidence of systemic inflammation is found, an echocardiogram should be obtained, even if the infants do not fulfill clinical criteria for KD. (3) Patient characteristics suggesting KD are listed in Table 59.2. Characteristics suggesting disease other than KD include exudative conjunctivitis, exudative pharyngitis, discrete intraoral lesions, bullous or vesicular rash, or generalized adenopathy. For these patients, one should consider alternative diagnoses (see Diagnosis and Differential Diagnosis, Table 59.3). (4) Supplemental laboratory criteria include albumin <3 g/dL, anemia for age, elevation of alanine aminotransferase, platelets after 7 days $>450,000/\text{mm}^3$, white blood cell count $\geq 15,000/\text{mm}^3$, and urine ≥ 10 white blood cells/HPF. (5) These patients can be treated before performing echocardiography. (6) Echocardiography is considered positive for purposes of this algorithm if any of three conditions are met: z-score of left anterior descending coronary artery (LAD) or RCA ≥ 2.5 , coronary arteries meet Japanese Ministry of Health criteria for aneurysms, or more than 3 other suggestive features exist including perivascular brightness, lack of tapering, decreased LV function, mitral regurgitation, pericardial effusion, or z-scores in LAD or RCA of 2 to 2.5. (7) If the echocardiogram is positive, treatment should be given to children within 10 days of fever onset and those beyond day 10 with clinical and laboratory signs (CRP, ESR) of ongoing inflammation. (8) Typical peeling begins under nail bed of fingers and then toes. CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; f/u, follow-up. (From Newburger JW, Takahashi M, Gerber MA, et al. Diagnosis, treatment, and long-term management of Kawasaki disease: a statement for health professionals from the Committee on Rheumatic Fever, Endocarditis and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Circulation* 2004;110:2747–2771, with permission.)

Figure 59.2. Representative electrocardiogram leads in a 4-month-old girl with Kawasaki disease recorded on illness days 17 and 20. The latter tracings show marked decrease in R-wave voltage (V2–V5), indicative of acute anterior wall infarction, which was proven at autopsy.

Myocardial infarctions present differently in childhood compared to adults, with the most common symptoms being shock, chest pain, vomiting, inconsolable crying, and abdominal pain; the authors are aware of one case of referred left otalgia as a presentation of myocardial ischemia in a toddler with KD. Chest pain is reported much less frequently in children younger than 4 years of age. Approximately one-third of the patients are asymptomatic at the time of infarction, which often occurs at rest or during sleep, and infrequently during exertion (82). Fatality associated with the first episode of myocardial infarction has been reported to be 22%, with a progressively worsening mortality rates with subsequent attacks. Giant aneurysms are associated with higher rates of mortality. Fortunately, survival rates at 10, 20, and 30 years after the onset of KD are good, reported at 95%, 88%, and 88%, respectively (83). Rarely, aneurysms may rupture and cause sudden death. In general, late consequences of KD are isolated to cardiovascular disease and occur only in patients who had coronary disease at presentation. Preexisting obstructions in two or more major coronary arteries or in the left main coronary artery are associated with increased mortality.

Electrocardiographic Features

During the acute phase of KD, the electrocardiogram (ECG) may show sinus tachycardia, prolongation of PR and corrected QT intervals, decreased QRS voltage, and T-wave flattening. The presence of large aneurysms may lead to acute myocardial infarction manifested as ST-segment elevation and inversion of T waves (Fig. 59.2). Thrombosis of an RCA aneurysm may produce a silent posterior wall infarction manifested as abnormally deep Q waves in leads II, III, and aVF. One report of invasive electrophysiology studies in patients with KD-related coronary disease demonstrated a high rate of a variety of conduction abnormalities and arrhythmias, including dual AV node and atrial fibrillation; the clinical implications of these findings outside the catheterization lab are unclear (84).

Radiologic Features

The chest radiograph is usually unremarkable, although transient cardiomegaly is seen in 20% of cases during the acute phase. Rarely, the chest x-ray may show localized pulmonary infiltration or pleural effusion. Patients whose coronary aneurysms persist ≥ 1 year after the onset of the disease may show a thin, eggshell-like calcification outlining the aneurysms.

Echocardiographic Features

Echocardiography is essential in the evaluation and management of KD. It is invaluable for detecting coronary artery aneurysms during the acute stage and should be performed at diagnosis to establish a baseline and in some cases to aid in diagnosis (Fig. 59.1). Findings of perivascular brightness, mild coronary artery ectasia, and lack of tapering of the coronary arteries are relatively common in the acute stage of KD, affecting as many as a third of patients (85). Decreased left ventricular contractility (20% of acute KD), diastolic dysfunction, mild valvular regurgitation (most commonly, mitral regurgitation in 25% of acute KD), and minor pericardial effusion also may be seen on echocardiography in acute KD (72,86). Myocardial dysfunction is associated with a greater risk of coronary artery dilation (72). Aortic regurgitation occurs rarely during the chronic phase (52). Echocardiography is usually repeated at 2 and 6 weeks after the onset of illness to see the extent of coronary involvement and to guide therapy. Echocardiograms may be done more frequently in patients who have a more complicated clinical course to help guide treatment. For patients with giant aneurysms, we perform echocardiograms twice weekly early in the illness, then weekly through the first 45 days of illness, monthly until the 3rd month, and then every 3 months for the first year to assess for thrombosis. For long-term cardiac follow-up, echocardiography is useful for evaluating global left ventricular function, regional wall motion characteristics, and competency of mitral and aortic valves. Proximal segments of the right and left coronary arteries may be visualized in nearly all patients. Visualization of distal coronary artery segments may be technically demanding, necessitating patient sedation, use of special views (87), and careful optimization of machine settings.

Capannari et al. (88) have shown that cross-sectional echocardiography has excellent sensitivity and acceptable specificity for detection of coronary aneurysms, as compared with coronary angiography. Standards published by the Japan Kawasaki Disease Research Committee use an empiric definition of abnormality (89). By these standards, a coronary artery is classified as abnormal if (a) the internal diameter is >3 mm in children younger than 5 years of age; (b) the internal diameter is >4 mm in children ≥ 5 years of age; (c) if the internal diameter of a segment measures 1.5 times that of an adjacent

segment; or (d) if the coronary artery lumen is clearly irregular. Nakano et al. (75) first noted that angiographically measured right and left coronary artery diameters correlated with BSA. In children with a BSA of $<0.5 \text{ m}^2$, coronary arteries measured $\leq 2.5 \text{ mm}$. In children with a BSA of 0.5 to 1 m^2 , coronary diameters were 2.5 to 3 mm in most cases. In children with a BSA $>1 \text{ m}^2$, coronary diameters were $\geq 3 \text{ mm}$. Published normative coronary artery dimensions by echocardiography encompass such a wide range of values that there is a significant overlap between normal and abnormal arteries (90–92). Using echocardiographic coronary artery measurements, de Zorzi et al. (91) reported that the BSA-adjusted internal diameters of coronary arteries of KD patients were significantly larger than a normal comparison group and that 27% of the patients classified as having normal coronary arteries by the Japanese Research Committee criteria would have had enlargement of at least one coronary by their new criteria, that is, $z\text{-score} \geq 2.5$ (Fig. 59.3). Therefore, an alternate aneurysm classification schema considers the size of the coronary in relation to the size of the patient (61). When $z\text{-scores}$ are used, the following cut-points have been proposed: a small aneurysm has $z\text{-score} \geq 2.5$ to <5.0 , a large aneurysm has a $z\text{-score} \geq 5.0$ to <10.0 , and a giant aneurysm has $z\text{-score} \geq 10.0$ (92).

Stress Testing

Cardiac stress testing for reversible ischemia should be performed in children with coronary aneurysms. Virtually all types of stress tests performed in adults with ischemic heart disease have been applied to the pediatric population. These include nuclear perfusion scans with exercise (93,94), exercise echocardiography (94), stress echocardiography using pharmacologic agents, such as dobutamine (95,96), dipyridamole, or adenosine (97), magnetic resonance stress imaging, with quantification of regional perfusion (98), and stress myocardial contrast echocardiography (99–101). The combination of resting and stress myocardial perfusion imaging using thallium 201 or a technetium-99m-based compound has high sensitivity but moderate to low specificity in detecting coronary artery obstruction (102). Nevertheless, the technique is useful in longitudinal follow-up of patients with known coronary pathology.

The predictive value of stress tests for coronary artery disease requiring intervention is a function of the probability of significant disease in the population tested (Bayes theorem). For example, false-positive tests are more likely in patients with a low prior probability of coronary disease. Used appropriately, the results of stress testing may guide the decision to refer a patient for invasive evaluation (i.e., cardiac catheterization) as well as for catheter or surgical intervention. The choice of stress modality should be guided by institutional expertise with particular techniques and by the age of the child (e.g., pharmacologic stress should be used in young children in whom traditional exercise protocols are not feasible). In the older child, exercise stress testing best simulates everyday life exposure and should be accompanied by some imaging technique to enhance sensitivity to detect ischemia. Post-exercise ECHO imaging has been trialed as a methodology for assessing for ischemia. Single-photon emission computed tomography (SPECT) perfusion imaging has also been used to demonstrate myocardial perfusion, particularly in experienced hands, and demonstrates differential response to the cold pressor test (103). There is no role for stress testing in children with KD who never had coronary artery abnormalities.

Cardiac Catheterization and Angiography

Cardiac catheterization and angiography may be helpful for determining prognosis and therapeutic strategy in children

Figure 59.3. Mean and prediction limits for 2 and 3 SDs for size of (A) LAD, (B) proximal RCA, and (C) LMCA according to body surface area for children <18 years old. LMCA $z\text{-scores}$ should not be based on dimension at orifice and immediate vicinity; enlargement of LMCA secondary to Kawasaki disease usually is associated with ectasia of LAD, LCX, or both. BSA, body surface area; LAD, left anterior descending coronary artery; LMCA, left main coronary artery; RCA, right coronary artery. (From Newburger JW, Takahashi M, Gerber MA, et al. Diagnosis, treatment, and long-term management of Kawasaki disease: a statement for health professionals from the Committee on Rheumatic Fever, Endocarditis and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Circulation* 2004;110:2747–2771, with permission.)

with echocardiographic evidence of large or multiple coronary artery aneurysms or with clinical, ECG, or stress test evidence of myocardial ischemia. Traditionally, catheterization has been an important adjunct in the long-term follow-up of patients with known coronary obstruction. However, newer methods of coronary artery visualization and a greater focus on functional testing are diminishing the frequency with which

invasive testing is required. There is little incremental value in angiography if echocardiography clearly shows a small solitary aneurysm in continuity with normal proximal and distal segments in an asymptomatic patient. Elective catheterizations are not recommended in the acute phase, in part due to lack of additional information gained, and because of the higher risk of arterial complications seen in acute KD (104). However, emergent catheterization may be necessary for therapeutic decision-making in cases where coronary artery thrombosis is suspected. Left ventricular end-diastolic pressure may be elevated in the presence of acute infarction or severe chronic ischemia.

If catheterization is necessary, the safety and efficacy of selective coronary arteriography in infants and children have been established. Selective coronary arteriography is advantageous over aortic root injection because aneurysms, obstructions, and collateral arteries can be precisely delineated. Such information may be helpful for planning treatment and post-treatment evaluation for coronary bypass surgery or thrombolytic therapy. More recently, interventional catheterizations are being applied to KD patients (see Treatment section below). Our current practice is to perform cardiac catheterization for angiography at 1 year after the onset of illness in patients with complex or large coronary aneurysms who cannot be imaged in other ways, who have symptoms of ischemia, or in whom findings would guide therapeutic decisions. Because peripheral artery aneurysms may occur, particularly in children with giant aneurysms, angiograms of peripheral arteries, including the subclavian arteries, internal mammary arteries, and iliac/femoral vessels should be performed in children undergoing radiographic coronary angiography.

Magnetic Resonance Imaging, Magnetic Resonance Angiography, and Computed Tomography

Magnetic resonance imaging (MRI) and computed tomography (CT) imaging modalities for diagnosing coronary artery lesions in KD are increasingly used as alternatives to traditional invasive angiography, particularly for assessment of coronary stenosis late in the clinical course. MRI has been shown to accurately image proximal segments of coronary arteries, including aneurysms, but not stenotic segments (105,106). During the acute phase, MRI may show marked enhancement of coronary vascular wall, probably reflecting vasculitis (107). A major drawback of the earlier generation of MRI was need for a prolonged voluntary breath-hold, making the examination of younger children difficult. However, more recent models have the capability to track and correct for the patient's respiratory movement. MRI can also incorporate functional testing using dobutamine or adenosine stress testing. Multidetector CT successfully identifies not only coronary artery aneurysms but also stenotic segments with sensitivity close to 90% (108,109), with one study showing that CT was in complete concordance with conventional angiography, while MRI failed to identify 7% of aneurysms and missed one stenosis (110). However, unlike MRI/magnetic resonance angiography (MRA), CT has the drawback of exposure to ionizing radiation—generally less than conventional cineangiography, but still a concern in the pediatric patient who might need serial coronary imaging.

Long-Term Cardiovascular Effects

Patients who have never had coronary artery aneurysms appear to have a good prognosis, with a standardized mortality ratio in Japan that is indistinguishable from the general population (5). Follow-up over 10 to 21 years of Japanese patients with KD,

including catheterization at 1 year, did not demonstrate any cardiac abnormalities among those whose coronary arteries had been normal earlier (111). However, lingering concern about late morbidity and subclinical abnormalities has prompted studies to examine preclinical vascular dysfunction in systemic arteries in KD patients who never were noted to have coronary artery abnormalities. Some studies reported abnormalities in noninvasive vascular testing, including brachial artery reactivity testing (112) and pulse wave velocity (113–115), while other studies do not confirm these results (116,117). Children who have recovered from KD may develop dyslipidemia in the form of mild to moderately low high-density lipoprotein that resolves gradually over years (118). Patients who have never had coronary abnormalities should be counseled on modifiable risk factors for future atherosclerotic cardiovascular disease.

Children who develop small- to medium-sized coronary artery aneurysms also tend to have good prognosis, at least through childhood, because their coronary arteries usually undergo regression to normal lumen diameter. Among coronary arterial segments with aneurysms, approximately half will regress to normal internal lumen diameter within 1 to 2 years (54,55,111). Figure 59.4 shows an example of dramatic regression of a complex aneurysm over a relatively short time. Factors favoring aneurysm regression include age of onset >1 year, female sex, fusiform shape of the aneurysm, and aneurysm diameter <8 mm. Regression appears to occur by neointimal thickening due to migration, transformation, and proliferation of smooth muscle cells derived from the tunica media (54) and replacement of the inflammation with fibroblasts and extracellular matrix. However, vessels with regressed aneurysms, even with normal appearing lumens, may have an abnormally thick intima-medial layer as seen by coronary intravascular ultrasonography (119), with thicker intima in vessels that had greater initial diameters (120). In addition, these vessels have a reduced capacity for vasodilation when challenged by infusion of nitrates (non-endothelium-dependent vasodilators) and may undergo paradoxical vasoconstriction in response to acetylcholine (an endothelium-dependent vasodilator) (121–123). Carotid ultrasound of individuals who had KD and coronary aneurysms showed thickened intimal-medial thickness (IMT), a sign of atherosclerosis, many years after the episode of KD (124). Other data showed greater arterial stiffness in KD patients 10 years after disease (125). A postmortem histologic study in children who died years later due to unrelated causes showed extensive intimal thickening in coronary artery segments (53). Thus, the coronary aneurysm that has regressed is not a normal coronary artery, even if the lumen size is normal angiographically.

Large or complex aneurysms are less likely to undergo regression and place patients at risk for ischemic heart disease. A history of KD in childhood may first be diagnosed when young adults present with angina or myocardial infarction and are found to have large coronary artery aneurysms (126,127). CRP levels are higher in patients with persistent coronary aneurysms compared to KD patients without aneurysms or normal controls (114,115).

Children who develop coronary aneurysms are at risk for increased mortality, with the highest hazard occurring secondary to coronary artery thrombosis in the period between 15 and 45 days after onset of KD (82). In the acute phase of illness, coronary thrombosis is promoted by increased number and activity of platelets, activated procoagulant endothelium, stagnation of blood flow within aneurysm, and abnormal vascular wall shear stress at the entrance of aneurysm. Later onset myocardial ischemia or infarction is more likely due to acute thrombosis at the site of progressive coronary artery stenosis due to myointimal proliferation; in severe cases, myocardial infarction or ischemic cardiomyopathy may result. According to a nationwide hospital survey in Japan, 73% of myocardial infarctions occurred during the first year after illness onset

Figure 59.4. Serial right coronary arteriograms in a boy who developed Kawasaki disease at 3 months of age. **A:** Right coronary arteriogram performed 3 months after the onset shows an extensive segmented aneurysm involving the entire right coronary artery. **B:** Follow-up study obtained 16 months later shows near-complete regression of the aneurysm. (From Takahashi M, Mason W, Lewis AB. Regression of coronary aneurysms in patients with Kawasaki syndrome. *Circulation* 1987;75:387–394, with permission.)

(82). However, fatal infarctions can occur many years and even decades after illness onset. Fortunately, spontaneous myocardial revascularization through formation of collateral arteries and recanalization is common (Fig. 59.5). Large aneurysms in the RCA are more likely than those in the left coronary artery

system to undergo thrombosis followed by recanalization in the form of braided small vessels, creating a unique pathologic phenomenon referred to as *arteriae in arteria* (arteries within an artery). However, aneurysms in either system may develop progressive focal stenosis (53).

Figure 59.5. Serial right coronary angiograms in a girl who developed Kawasaki disease at 2 months of age. **A:** Right coronary arteriogram obtained 8 months after the onset shows two large saccular aneurysms. **B:** Follow-up right coronary arteriogram 3.5 years later shows thrombotic obstruction of both aneurysms. The distal right coronary artery is opacified via tortuous recanalized arteries.

Children with a history of KD coronary aneurysms, whether regressed or persistent, are considered to be “at risk” for early atherosclerosis by the AHA (128). AHA pharmacologic treatment thresholds for cardiovascular risk factors such as hypertension or hyperlipidemia are lower in KD patients with aneurysms compared to the general population (128). These guidelines are based on expert consensus, because rigorous trial data remain unavailable at present but data from preclinical testing noted above and one small interventional trial of statins in KD patients support these recommendations. Fluvastatin use improved a variety of noninvasive indicators of vascular dysfunction in a small series of children with significant KD coronary aneurysms (129).

TREATMENT: ACUTE PHASE

Intravenous Immunoglobulin

The standard of care for treatment of acute KD is high-dose IVIG together with aspirin. High-dose IVIG has been shown in many clinical trials to reduce the incidence of coronary aneurysms from 25% to 30% to <5% when administered ≤ 7 to 10 days of the disease onset (130). Meta-analysis shows a dose-response effect for IVIG, with low doses being relatively ineffective while a high dose of 2 g/kg as a single infusion is the most effective, of the doses trialed (131). Because patients with KD often have diminished left ventricular contractility, IVIG is administered slowly, over 8 to 12 hours to minimize the chance of hypersensitivity or hyperpyrexia reaction and to prevent solute overloading. A 5% solution of IVIG has osmolality equivalent to normal saline.

Treatment with IVIG should be administered to all children with KD within the first 10 days of illness, and ideally in the first 7 days (Table 59.5). IVIG should also be administered to those beyond illness day 10 in whom fever persists or who have coronary artery abnormalities together with persistent clinical and laboratory evidence of inflammation. Persistent fever after IVIG treatment is related to a higher risk of coronary aneurysms and therefore, although randomized trials are lacking, most experts believe that children who are febrile without other explanation more than 36 hours after completion of the first IVIG infusion should be retreated with IVIG, 2 g/kg, as a single infusion. A retrospective review of risk factors for aneurysms among KD patients treated with an additional dose of IVIG showed that the number of days of fever before initiation of IVIG retreatment was an independent predictor of coronary aneurysms (132), with treatment within 10 days leading to a significant reduction in coronary aneurysms (fivefold). The exact mechanism of immunoglobulin action in this setting remains unknown.

Adverse effects of IVIG include anaphylaxis, hypotension, rigors, headache, and hemolytic anemia. Many physicians prescribe IV diphenhydramine, 1 mg/kg, to a maximum of 50 mg, prior to IVIG infusion, to reduce the likelihood of allergic reactions. Measles and varicella immunizations should not be given for 11 months after IVIG treatment because of a risk of inadequate immunoresponse, unless the risk of exposure is considered to be high. If these vaccines are given earlier, the serologic response should be assessed, and, if inadequate, the child should be reimmunized at least 11 months after IVIG administration.

For children who defervesce with a second IVIG infusion, but in whom fever recurs, alternate therapies must be considered (see below, Other Anti-inflammatory Therapies). Retrospective data suggest persistent fever despite IVIG therapy is higher in males and in those who have lower albumin, higher AST levels, and CRP ≥ 8 mg/dL after IVIG infusion (133,134).

TABLE 59.5 Treatment of Kawasaki Disease During the Acute Phase

Initial anti-inflammatory treatment: intravenous immunoglobulin (IVIG) plus high-dose aspirin

IVIG dosage: 2 g/kg as single infusion over 8–12 h

Aspirin dosage: 80–100 mg/kg/d orally in four divided doses given every 6 h until the patient is afebrile for 48 h

In case of persistent or recrudescence fever:

Repeat dose of IVIG 2 g/kg as single infusion; consider IV methylprednisolone 30 mg/kg once a day; may be repeated as necessary up to a total of three doses

Subsequent antiplatelet treatment:

Aspirin 3–5 mg/kg orally once daily

Duration of treatment: 6–8 wk from onset or until sedimentation rate and platelet count return to normal; aspirin is discontinued at this point, if no coronary artery abnormalities are observed on echocardiogram

Continued indefinitely if coronary abnormalities are observed

If large aneurysms are noted with or without thrombus:

Start IV heparin or subcutaneous low-molecular-weight heparin

Start warfarin and titrate dose (target INR 2–2.5); continue low-dose aspirin at the same time

Following IVIG administration, immunization of the patient with live virus vaccine such as measles, mumps, and rubella (MMR) should be delayed by 11 mo or until the antibody titer has returned to a very low level

Several algorithms have been proposed to predict resistance to IVIG (135); however, the sensitivity of these algorithms in North American populations is currently too low to make the scores clinically useful (133).

Aspirin and Other Antithrombotic Therapies

Aspirin is used in high dose (80 to 100 mg/kg/d, divided into four daily doses) early in the disease for its anti-inflammatory and antipyretic effects (136). It should be noted that aspirin does not influence the incidence of coronary artery aneurysms (131). Its safety and efficacy relative to other antipyretic or anti-inflammatory agents in the acute phase of the disease have not been tested prospectively, and retrospective data suggest that high-dose aspirin use may not have advantages over other agents (131). However, ibuprofen has been shown to antagonize the irreversible platelet inhibition induced by aspirin (137). Thus, short-term use of high-dose aspirin for its anti-inflammatory, analgesic, and antipyretic effects remains a reasonable therapeutic strategy. Blood salicylate level and liver function tests should be checked if the patient remains on high-dose aspirin for >3 days to avoid salicylate intoxication, although gastrointestinal absorption of aspirin is generally decreased during the acute phase. After fever has resolved for ≥ 48 hours, the aspirin dose is lowered to 3 to 5 mg/kg/d for its antiplatelet effects. Low-dose aspirin is administered for approximately 6 weeks and then discontinued in patients without coronary artery aneurysms.

In children with small coronary aneurysms, low-dose aspirin is generally sufficient as monotherapy to prevent thrombosis. Aneurysms that are moderate or large, with maximal internal diameter 5 to 7 mm or z -score 7 to 9, are often treated with dual antiplatelet therapy, for example, low-dose aspirin and clopidogrel; without clinical trial evidence to support this approach, care is individualized. For high-risk coronary lesions, including giant aneurysms (≥ 8 mm or z -score ≥ 10), warfarin is often used. The use of warfarin in this context is associated with a lower rate of myocardial infarction compared to aspirin (138). Low-molecular-weight heparin is usually substituted for warfarin in infants to lessen the number of blood draws necessary for monitoring; outcomes seem to be at least as good, or possibly better with low-molecular-weight heparin (139).

Reye syndrome has been reported in children with KD taking high-dose aspirin (140). Although Reye syndrome has not been associated with use of low-dose aspirin, an annual influenza vaccine is recommended for all children on chronic aspirin therapy. When a child on chronic aspirin therapy develops a flu-like illness, aspirin should be withheld transiently and, if necessary, another antiplatelet medication (e.g., dipyridamole or clopidogrel) should be substituted until resolution of the illness.

Supportive Care

Intravenous fluid is often necessary because of poor oral intake and increased insensible losses. The patient should be kept comfortable in a quiet semidark room because of photophobia and irritability. Topical skin and mouth care should be provided to relieve itching and soreness in the lips and oral mucosa. As above, the use of ibuprofen is not advised in patients with coronary aneurysms, due to some evidence demonstrating an inhibition of the antiplatelet effects of aspirin in the acute phase of KD (141).

Other Anti-Inflammatory Therapies

If two courses of IVIG are not sufficient, other anti-inflammatory therapies may be considered. Corticosteroids have been administered to children with KD both as primary therapy and as rescue therapy (142), with mixed support. One early trial in Japan assessing primary therapy suggested that steroids increased the incidence of coronary artery aneurysms. Several subsequent studies have suggested that primary steroid therapy may shorten the length of fever and diminish the inflammatory response. Because the data on IVIG efficacy are so clear, steroids are no longer considered reasonable monotherapy. However, steroids have been evaluated in a number of retrospective studies and case series as rescue therapy to patients with IVIG-resistant KD, with conflicting results. Steroid therapy alternately improves fever and the inflammatory response (142–144), or prolongs fever and lowers rates of aneurysm regression (145). The influence of primary pulse steroid therapy given together with high-dose IVIG and aspirin on coronary artery outcome was investigated in a multicenter double-blind placebo-controlled randomized trial (146). Although inclusion of steroids in the primary therapy tended to result in more rapid recovery of ESR and CRP and shorter initial hospital stay, there was no difference in coronary outcome. Based on currently available literature, treatment with intravenous methylprednisolone 30 mg/kg (142) should be reserved for children who have persistent or recrudescence fever despite at least two courses of IVIG, 2 g/kg.

In addition to steroids, other anti-inflammatory therapies have been considered for recalcitrant cases of KD. Options include a third IVIG infusion, abciximab in patients with

persistent aneurysms, infliximab, and agents borrowed from rheumatologic treatments (147). Abciximab is a chimeric human-murine monoclonal antibody to platelet glycoprotein IIb/IIIa receptor. It has been used as therapy for enlarging coronary artery aneurysms in the acute phase of KD, and also to treat clots in patients with KD, late or early. Compared with historical controls in a single-center experience, patients with coronary aneurysms who received abciximab in the acute or subacute phase of KD showed greater regression in maximal aneurysm diameter (148), and at late follow-up of 3 to 5 years (149). The exact mechanism of this possible effect on aneurysm regression is unknown, but it may involve promotion of vascular remodeling through secondary anti-inflammatory effects.

Methotrexate has also been used in recalcitrant KD, with good retrospective data showing faster resolution of fever and lower CRP. No difference in the coronary artery status was demonstrated (150).

Because TNF- α levels are elevated in children with KD, investigation into therapies directed against TNF- α is the subject of considerable interest. High-dose pentoxifylline, when administered together with standard therapy, was associated with a lower prevalence of coronary aneurysms than standard therapy alone (151). Infliximab is a chimeric monoclonal antibody to TNF- α that may reduce circulating cytokines. Its use in KD has also been reported (152,153); a retrospective review of infliximab versus IVIG as a treatment for recurrent fever in children treated once with IVIG showed a shorter duration of fever compared to second IVIG dosing. No differences were seen in coronary artery dimensions; however, the study was not sufficiently powered to examine this question definitively (154). Etanercept is a TNF- α receptor blocker used in juvenile rheumatoid arthritis when methotrexate is insufficient (155). A small Phase I open-label study suggested etanercept appeared to be generally safe as an additional therapy in patients who receive IVIG and high-dose aspirin (156). In this study, one patient with meningococemia was notably mistakenly diagnosed as KD, serving as a warning to clinicians that powerful immunosuppressant therapies should be used only in patients with indisputable diagnoses of KD. Double-blind randomized controlled trials of primary therapy with etanercept and infliximab each are ongoing (157,158).

Finally, plasma exchange has been reported to lower the incidence of coronary artery aneurysms in uncontrolled studies (159–161). Because of the technical complexity of this therapy, it should be used only when other methods have failed. Rarely, cytotoxic agents have been used to treat patients with refractory acute KD (162,163), but the risks of such therapies exceed their benefits for the vast majority of patients.

TREATMENT: CHRONIC PHASE

Coronary Risk Stratification

Long-term management of patients with KD and coronary aneurysms should be tailored to each patient's estimated risk level for ischemic heart disease. Despite the lack of actuarial data in KD, attempts have been made to stratify patients' coronary risks based on echocardiographic or angiographic findings. Such an empiric risk stratification published by a committee of the AHA (61) may serve as an interim guide in patient management issues such as antiplatelet or anticoagulant therapy, restriction of physical activities, frequency of cardiac evaluation, and types of diagnostic tests, including coronary angiography (Table 59.6). A patient's overall risk may decrease or increase over time depending on whether the coronary artery aneurysm(s) undergo regression or develop an obstructive lesion.

TABLE 59.6 Coronary Risk Stratification

Risk Level	Pharmacologic Therapy	Physical Activity	Follow-up and Diagnostic Testing	Invasive Testing
I (no coronary artery changes at any stage of illness)	None beyond first 6–8 wk	No restrictions beyond first 6–8 wk	Cardiovascular risk assessment, counseling at 5-y intervals	None recommended
II (transient coronary artery ectasia disappears within first 6–8 wk)	None beyond first 6–8 wk	No restrictions beyond first 6–8 wk	Cardiovascular risk assessment, counseling at 3- to 5-y intervals	None recommended
III (1 small–medium coronary artery aneurysm/major coronary artery)	Low-dose aspirin (3–5 mg/kg aspirin/d), at least until aneurysm regression documented	For patients <11 y old, no restriction beyond first 6–8 wk; patients 11–20 y old, physical activity guided by biennial stress test, evaluation of myocardial perfusion scan; contact or high-impact sports discouraged for patients taking antiplatelet agents	Annual cardiology follow-up with echocardiogram + ECG, combined with cardiovascular risk assessment, counseling; biennial stress test/evaluation of myocardial perfusion scan	Angiography, if noninvasive test suggests ischemia
IV (≥ 1 large or giant coronary artery aneurysm, or multiple or complex aneurysms in same coronary artery, without obstruction)	Long-term antiplatelet therapy and warfarin (target INR 2.0–2.5) or low-molecular-weight heparin (target: anti-factor Xa level 0.5–1.0 U/mL) should be combined in giant aneurysms	Contact or high-impact sports should be avoided because of risk of bleeding; other physical activity recommendations guided by stress test/evaluation of myocardial perfusion scan outcome	Biannual follow-up with echocardiogram + ECG; annual stress test/evaluation of myocardial perfusion scan	First angiography at 6–12 mo or sooner if clinically indicated; repeated angiography if noninvasive test, clinical, or laboratory findings suggest ischemia; elective repeat angiography under some circumstances (see text)
V (coronary artery obstruction)	Long-term low-dose aspirin; warfarin or low-molecular-weight heparin if giant aneurysm persists; consider use of β -blockers to reduce myocardial O ₂ consumption	Contact or high-impact sports should be avoided because of risk of bleeding; other physical activity recommendations guided by stress test/myocardial perfusion scan outcome	Biannual follow-up with echocardiogram and ECG; annual stress test/evaluation of myocardial perfusion scan	Angiography recommended to address therapeutic options

Diagnosis, treatment, and long-term management of Kawasaki disease: a statement for health professionals from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Circulation* 2004;110:2747–2771, with permission.

Anticoagulation for Giant Aneurysms

Giant aneurysms are particularly susceptible to thrombotic occlusion, with the overall probability of either complete thrombotic occlusion, severe stenosis requiring surgery, or death caused by myocardial infarction estimated to be about 7.5% per year for KD patients with giant aneurysms treated with aspirin therapy alone. A retrospective chart review showed the use of warfarin likely improved event-free survival without risk of significant bleeding episodes (Fig. 59.6). (138). We recommend patients with giant aneurysms be anticoagulated with either warfarin to an international normalized ratio (INR) range of 2 to 2.5 or low-molecular-weight heparin, in combination with low-dose aspirin.

Management of Coronary Thrombosis

In the event of myocardial infarction secondary to acute coronary artery thrombosis substantiated by ECG findings and elevated troponin T or I, the treatment of choice is catheterization to restore coronary perfusion. If sufficient expertise in interventional catheterization is not immediately available, or the patient is too small to undergo transcatheter restoration of coronary blood flow, thrombolytic therapy should be administered with alteplase, a recombinant tissue plasminogen activator, at 0.5 mg/kg/h intravenously for 6 hours, low-dose aspirin 3 to 5 mg/kg, and therapeutic heparin infusion to achieve a PTT of 50 to 70 seconds (164). Even in the absence of clinical infarction, acute development of a large thrombus within the aneurysm lumen is an indication for thrombolysis. After 6 hours, treatment should be continued based on reassessment of the thrombus and clinical picture. Blood fibrinogen level, activated partial thromboplastin time, and fibrin degradation products must be monitored. Patients with a particularly large thrombus burden may be appropriate for intravenous alteplase given at half dose (0.25 mg/kg/h), together with abciximab (platelet glycoprotein IIb/IIIa inhibitor), as an initial bolus of 0.25 mg/kg bolus over 30 minutes, followed by an infusion of 0.125 μ g/kg/min for 12 hours. Abciximab may be given together with low-dose heparin (10 U/kg/h) to prevent clot extension in acute KD to treat mural thrombus. The

progress of therapy with thrombolytic agents or abciximab should be followed by serial echocardiography or, if needed, coronary arteriography, and all decisions need to be made the context of the specific clinical circumstances.

Surgical and Transcatheter Revascularization

Because evidence-based data in KD patients are limited, recommendations for surgical and percutaneous revascularization in patients with KD coronary artery aneurysms are based upon expert consensus, retrospective series, and adult atherosclerotic coronary artery disease experience. Indeed, coronary revascularization in KD patients is too rare to be studied with adequate power in randomized trials. In principle, coronary bypass surgery or transcatheter revascularization should be performed with the goal of relieving symptoms of angina and reducing the risk of myocardial infarction or sudden death. For the most part, such procedures should be performed in patients with coronary artery sequelae of KD who have angina and/or a risk of subsequent myocardial infarction after stress testing has revealed reversible ischemia (165–167). Decisions about revascularization should always be made in concert with experts in adult interventional cardiology and cardiovascular surgery.

Japanese guidelines suggest surgical revascularization for those patients who have high-grade obstructions in at least two major coronary arteries or in the left main coronary artery because of the high risk of fatal or incapacitating myocardial infarction (168). These guidelines also suggest that patients with high-grade stenosis in the left anterior descending artery should undergo surgery. However, indications for surgery must be considered on a case-by-case basis. Of note, as is the case in adults with atherosclerotic coronary disease, lesions with competitive flow through collaterals are more likely to have graft stenosis or development of a “string sign” and are less likely to benefit from coronary artery bypass grafting (CABG) (169). Indeed, in a recent Japanese series, patients whose interventions were performed in the absence of ischemic findings had higher rates of reinterventions (169).

Fortunately, mortality and morbidity rates after CABG are low, and complications of CABG can often be managed with percutaneous intervention. Late patient survival rates after the CABG procedure have been reported to be 95% at 25 years, with event-free survival rates of approximately 60% (170). In the single-center experience of Kitamura et al. (165,170), the use of internal thoracic arteries resulted in nearly 100% 1-year graft patency and documented the growth of the graft over time, in keeping with the somatic growth. In contrast, saphenous vein grafts had only a 50% 1-year patency rate. The patient's age also influenced graft patency rate with children over 12 years having higher graft patency than those under age 12 years (95% and 91% vs. 93% and 63%, respectively).

Percutaneous intervention is increasingly used as a substitute for CABG. Indications for angioplasty in adults with atherosclerotic coronary artery disease should be considered in the management of patients with KD. In addition, the Japanese Ministry of Health has published indications for percutaneous intervention that include (a) ischemic symptoms, (b) stress testing revealing reversible ischemia, and (c) 75% stenosis of the LAD. These guidelines recommend surgical revascularization when there is significant left ventricular dysfunction, or long-segment, complex, or ostial lesions, provided that there is viable myocardium distal to the obstruction (168). Early reports suggested that percutaneous revascularization had success rates equivalent to surgical methods but was associated with the need for more reinterventions (171,172). A recent multicenter survey in Japan noted that patients treated by percutaneous intervention, compared to

Figure 59.6. Kaplan–Meier event-free survival estimates of two groups of patients with giant coronary artery aneurysms: one group (historical control; $n = 11$) treated with aspirin only (shown in blue) and the other group ($n = 18$) treated with warfarin and aspirin (shown in red). The warfarin group appears to have longer survival to composite end points of total thrombotic occlusion, severe coronary artery stenosis requiring surgical intervention, or death owing to myocardial infarction. ASA, acetylsalicylic acid (aspirin).

CABG procedure, had similar mortality and rates of acute myocardial infarction, but were more likely to require repeat revascularization (169,173). Long-term outcomes of KD patients after myocardial infarction are related to post-infarct left ventricular ejection fraction, and ventricular arrhythmia rates are significant in those with decreased ejection fraction (172). Finally, cardiac transplantation is an option for some patients with ischemic cardiomyopathy not amenable to percutaneous or surgical revascularization.

Rheumatic Fever and Rheumatic Heart Disease

Lloyd Y. Tani

Acute rheumatic fever (RF) occurs as a result of a complex interaction between group A streptococcus (GAS), a susceptible host, and the environment. An abnormal immune response to GAS infection leads to an acute inflammatory illness that most commonly affects the joints, brain, heart, and/or skin. Although the other manifestations are self-limiting and resolve without sequelae, carditis may result in chronic rheumatic heart disease (RHD) with associated significant morbidity and mortality. The degree of cardiac involvement is quite variable, ranging from mild, asymptomatic valvulitis to severe carditis with significant acute mitral and/or aortic regurgitation resulting in heart failure. The acute rheumatic cardiac involvement may resolve or persist and evolve into chronic rheumatic valvular disease, with cardiac symptoms developing years after the initial episode.

EPIDEMIOLOGY

Scope of the Problem

RF continues to be a major public health problem in developing countries, where it is the most common cause of acquired cardiac disease in children and young adults (1–7). Worldwide, it is estimated that at least 470,000 cases of RF occur annually in patients of all ages, with approximately 340,000 cases occurring in children 5 to 14 years of age. The majority of cases occur in developing countries and in indigenous populations, where the reported incidence is as high as 200 to 300 per 100,000 (4–6,8). Because of the difficulty in obtaining data in these regions and populations, it is possible that the true incidence in some areas is even higher; community-based surveillance suggests that the true incidence in some settings may be as high as 500/100,000 (9,10). In these regions, the current situation is similar to that experienced by developed countries in the early part of the 20th century.

In sharp contrast, there has been a significant decline in the incidence of RF and RHD over the last 50 years in most developed countries of the world (Fig. 60.1). The initial decline, which began prior to the initiation of penicillin, was at least partly due to improved socioeconomic conditions. With the subsequent initiation of penicillin, there was further acceleration in the rate of decline of RF (11,12). Changes in streptococcal strains and decreased virulence may have also contributed to the decline in RF seen in these countries (13). These changes have resulted in a marked decline in the mortality due to acute rheumatic carditis from 8% to 30% to nearly zero (11,12). In fact, the decrease in the incidence of RF in developed countries was so dramatic that the disease was thought to have “virtually disappeared” by the early 1980s (12).

In the mid-1980s, several sites in the United States reported focal outbreaks or resurgences of RF activity (14–19), and by 1988, a survey of pediatric cardiologists revealed a 5 to

12 times increased incidence of RF in 24 states (20). Unique features of this resurgence included the following: (a) many cases came from suburban/rural neighborhoods; (b) the majority of patients were Caucasian and from middle-class families with medical insurance and ready access to medical care; (c) there was no clear-cut evidence of crowding; and (d) a preceding sore throat prompting the patient and family to seek medical attention was relatively uncommon. Although the reason(s) for these resurgences is unclear, the appearance of certain strains of GAS (in particular heavily encapsulated or mucoid strains) in the community coincident with the reported resurgence in Utah supports the concept of “rheumatogenicity” (21). Despite these resurgences, the incidence of RF in developed countries is much lower than in developing countries, and has been estimated at 0.5 to 3 per 100,000 population (7,12,22,23).

The prevalence of RHD parallels the reported incidences of RF. Both RF and RHD continue essentially unabated in many developing countries of the world, where RHD remains an important and significant cause of morbidity and mortality (Fig. 60.2). Worldwide, it is estimated that 15 to 20 million people have RHD (7), of whom about 2.4 million are children between the ages of 5 and 14 years (8). Given the current estimates of RF incidence and the proportion of patients who develop RHD, it is estimated that at least 282,000 people develop RHD each year (8). The prevalence of RHD varies greatly between countries, ranging from <0.5/1,000 in developed countries of the world (8) to 78/1,000 in Samoa (24), and increases with age, peaking in young adults aged 25 to 34 years (10). The older prevalence data based on clinically detected RHD may significantly underestimate the true disease burden. Recent studies using echocardiography reported prevalences on the order of 10-fold greater than that detected clinically, suggesting that approximately 90% of RHD cases are subclinical (25).

Compared to cases occurring in industrialized countries, the initial episode of RF in developing countries occurs at a younger age, and often goes unnoticed. In these settings, it has been estimated that as many as 50% or more of patients are unaware of their disease and as many as 70% do not receive secondary prophylaxis (6). Compared to the natural history in developed countries, chronic RHD in developing countries occurs earlier, evolves more rapidly, is of greater severity, and more commonly leads to heart failure with its associated morbidity and mortality (2,26–31). Once significant RHD has developed, the methods for providing care to such patients are also limited in many of these developing countries. In 1994, it was estimated that at least 3 million people with RHD required repeated hospitalization for heart failure (6). In developing countries, 12% to 65% of all cardiac admissions are for RHD, with an average length of stay of 3 to 4 weeks, resulting in absence from work and reduced productivity (2,32). In 2001, an estimated 6.6 million disability-adjusted life years were lost to RHD. The mortality rate from RHD has been

Figure 60.1. Crude death rates from RF, United States, 1910 to 1977. (From Gordis L. The virtual disappearance of rheumatic fever in the United States: Lessons in the rise and fall of disease. T. Duckett Jones memorial lecture. *Circulation* 1985;72:1155–1162, with permission.)

estimated to range from 0.9 to 8.0 per 100,000 population (6,7,33,34). Based on conservative estimates, a minimum of 1.5% of patients with RHD die each year in developing countries where secondary prophylaxis is uncommonly given and medical and surgical treatments are often unavailable. Worldwide, it has been estimated that 233,000 to 492,000 deaths per year occur due to RHD, with 95% of the mortality occurring in developing countries (8). Further, patients with RHD are at increased risk for endocarditis and stroke, and complications associated with additional morbidity and mortality (8,31). In contrast, an analysis of more than 2.5 million hospital discharges in 2000 from 2,784 institutions in 27 states in the United States reported only 503 hospitalizations for RF among children <21 years (35).

Environment

Despite the epidemiologic link between GAS pharyngitis and RF, other factors clearly influence the incidence of RF. Current data suggest that the incidence of GAS pharyngitis has remained more or less stable in most countries, and that there has been no change in host resistance to the GAS organism. Therefore, the marked differences in the incidence of RF and prevalence of RHD in developing versus developed countries are likely due to other factors. The importance of environmental and socioeconomic factors in the epidemiology and pathogenesis of RF has been recognized for decades. In developing countries, overcrowding, poverty, poor nutrition, poor hygiene, and poor access to health care are common and

Figure 60.2. Prevalence of RHD in children aged 5 to 14 years. (Reprinted from Carapetis JR, Steer AC, Mulholland EK, et al. The global burden of group A streptococcal diseases. *Lancet Infect Disease* 2005;5:685–694, with permission from Elsevier.)

contribute to rapid spread (respiratory droplets) and increased virulence of GAS (36,37). In particular, overcrowding appears to be a major factor contributing to the high incidence of RF in many parts of the world. With poor access to health care, GAS pharyngitis is less likely to be diagnosed and treated, precluding effective primary prevention of RF. In addition, because cases of RF are more likely to go unnoticed, secondary prophylaxis is not implemented and RF recurrences are common.

The seasonal variation of RF in the temperate climates parallels that of GAS pharyngitis. Both GAS pharyngitis and RF are more common during the winter and spring in temperate climates, but there is no consistent seasonal pattern in the tropics. Geographically, RF occurs in all latitudes and altitudes (36).

Host

Children between the ages of 5 and 15 years are most commonly affected. RF is uncommon before age 5 years, almost never occurs before 2 years of age, and is uncommon beyond the age of 35 years (4). Children with RF before age 5 years commonly present with arthritis and rarely present with chorea; when present, cardiac involvement is more severe than in older children and persistent RHD is common (38,39). Adults with a primary episode of RF are much more likely to have joint manifestations than cardiac involvement (40). Recurrences are most frequent during adolescence and early adulthood. With the exception that chorea is more common in girls, there is no definite gender predisposition (41–44).

There is evidence supporting the importance of a host predisposition to developing RF. First, only a small minority of patients with streptococcal pharyngitis develops RF, even during streptococcal epidemics (~3%). Second, the incidence of recurrent RF in patients with a previous history of RF with cardiac involvement is as high as 50% following GAS pharyngitis (45–47). Third, studies indicate a familial predilection (48,49) and a higher concordance rate between identical twins than in fraternal twins (18.7% vs. 2.5%) (50,51). Higher rates of RF and RHD have also been reported in certain ethnic groups, specifically Maoris and Pacific Islanders in New Zealand, Samoans in Samoa and Hawaii, and Aboriginal people in Australia (50,52–54). (See section on “Susceptible Host” in the “Pathogenesis” section below.)

Streptococcal Infection

Most children have at least one episode of pharyngitis per year, approximately 10% to 30% of which are due to GAS, the most common bacterial cause of pharyngitis (55,56). Streptococcal pharyngitis occurs most commonly in children aged 5 to 15 years, and is uncommon before age of 2 years. Although GAS may be present in the pharynx with either true infection and pharyngitis or a carrier state, only true infection results in an immune response and risk for the development of RF (57). The prevalence of GAS carrier state varies considerably (5% to 30%), depending on the population and series (58,59). Approximately 0.3% (during nonepidemic) to 3.0% to 5.0% (during streptococcal epidemics) of individuals who have not had RF will develop the illness following an untreated symptomatic or asymptomatic streptococcal pharyngitis. Older studies reported a relationship between the clinical severity of the pharyngitis and likelihood of developing RF, but recent reports emphasize that RF occurs following very mild or asymptomatic pharyngitis in up to two-thirds of cases (14,60).

The strain and virulence of the streptococcal organism influence the likelihood of development of RF. In the 1930s, GAS strains that reactivated RF were noted to be different from strains that did not (61). Other investigators subsequently

found that some strains were associated with pharyngitis, while other strains were associated with skin infections (62). Further, certain GAS strains have been associated with RF, while others have been associated with poststreptococcal glomerulonephritis (63). Based on epidemiologic data, certain GAS strains are more likely to lead to RF (“rheumatogenic”) than others (“nonrheumatogenic”) (41,62,64). The M protein is thought to be a major virulence factor because it affects the ability of host cells to undergo phagocytosis. Of the greater than 130 M types, M types 1, 3, 5, 6, 14, 18, 19, 24, 27, and 29 have been associated with outbreaks of RF, while M types 2, 4, 12, 22, and 28 rarely lead to RF (7,13,65,66). Further evidence of the importance of the M protein came from the discovery that epitopes of the M protein molecule cross-react antigenically with human heart and brain tissue. Recent reports have also emphasized the association between the appearance of heavily encapsulated (“mucoid”) strains in a community and an increase in the number of RF cases (21,67–71). Finally, there is evidence that the decrease in the incidence of RF in developed countries is in part due to a change in GAS strains (altered expression of M protein) and a decrease in the incidence of GAS pharyngitis caused by rheumatogenic strains (13).

Despite the evidence for GAS pharyngitis but not impetigo as the initiating event leading to RF, there is some recent epidemiologic evidence to suggest that skin strains may play a role in some populations. In the Aboriginal population of Australia where RF is endemic, GAS impetigo is common but GAS pharyngitis is uncommon. Although direct causation, immune priming, and movement of strains from the skin to the pharynx have been postulated, the precise role of GAS skin infections in the pathogenesis of RF remains to be elucidated (72–74).

PATHOGENESIS

Organism

RF occurs as a result of a complex interaction between the GAS organism, host, and environment. Although the relationship to a preceding streptococcal pharyngitis is established and well accepted, the pathogenesis of RF is still not completely understood. Initially thought to occur as a result of direct injury by the GAS or its toxins, the organism has not been isolated from the organ systems of affected individuals. Current evidence strongly suggests that RF occurs as a delayed autoimmune response to pharyngitis caused by a rheumatogenic strain of GAS in a susceptible individual. Streptococcal antigenic components mimic normal human tissue antigens, leading to abnormal autoimmune humoral and cellular responses (molecular mimicry). Several lines of evidence lead to and support the concept of RF occurring after GAS pharyngitis: (a) documented relationship between GAS pharyngitis epidemics and RF (11,36), (b) immunologic evidence of a preceding streptococcal infection via elevated/rising antibody titers (75), (c) adequate treatment of GAS pharyngitis preventing the RF (76,77), (d) antibiotic prophylaxis preventing RF recurrences (78–80), and (e) mass prophylaxis with penicillin-terminated RF epidemics in military and civilian populations (81–83).

Susceptible Host

Most of the clinical manifestations of RF occur approximately 10 days to 5 weeks (average 18 days) following GAS pharyngitis in a susceptible host (84). A number of sources support the importance of host susceptibility in the pathogenesis of RF (see “Epidemiology” section above), and studies suggest that the abnormal immune response to GAS infection is genetically

controlled. The major contributors to the autoimmune reaction in RF/RHD are the major histocompatibility complex HLA class II alleles (DR, DQ) located on human chromosome 6. Several HLA class II alleles have been associated with a greater likelihood of development of RF/RHD in different countries. Expressed on the surface of cells that present antigens, these HLA molecules are thought to participate in the development of both the humoral and cell-mediated responses to certain streptococcal antigens. It is thought that HLA molecules might be involved with inappropriate activation of T cells that have the ability to cross-react with streptococcal and self-antigens that have some similarities (molecular mimicry) (85–90).

Several studies have shown a difference in the expression of a specific B-cell alloantigen detected by monoclonal antibody (D8/17) between patients with RF/RHD and control patients. In most of these studies, D8/17 is expressed in >85% of RF patients, but <15% of controls. Furthermore, D8/17 expression has also been found to be higher in first-degree relatives of RF patients than in controls. A few studies have failed to confirm this association, possibly related to population differences. At present, the role of B-cell expression of this alloantigen in the immune response to GAS remains unclear, and there is no correlation between expression and clinical outcome (91–94). Clearly, this is an area that requires more study.

Other components of the immune response are being evaluated. There is some evidence for polymorphisms in the gene for tumor necrosis factor alpha (TNF- α) and RHD. Among individuals who have had RF, there is some evidence for genetic differences between those who develop rheumatic valvular disease and those who have had RF without associated RHD (e.g., angiotensin-converting enzyme polymorphisms) (95–97).

Immunopathogenesis

Although our understanding of the pathogenesis of RF and RHD is incomplete, the importance of the host immune response to a preceding GAS infection is clear. Current evidence supports the following:

- GAS pharyngitis in a genetically susceptible host leads to breakdown products and streptococcal antigens that are cross-reactive with heart proteins (molecular mimicry) (98,99).
- The immune response that occurs in response to the infection leads to cross-reactive antibodies and cytokine production (100,101).
- The antibodies bind to the endothelial valve surface resulting in injury, cellular infiltration of inflammatory cells, and upregulation of vascular cell adhesion molecule 1 (VCAM-1), which aids in the recruitment and infiltration of T cells and macrophages, leading to further inflammation and damage (102).
- Endothelial injury exposes subendothelial structures and proteins including vimentin (found in cardiac fibroblasts) and laminin (extracellular matrix protein present in the basement membrane of valves and around endothelium).
- Inflammation leads to neovascularization, allowing further recruitment of T cells, leading to granulomatous inflammation and many of the changes seen with chronic RHD.
- Cellular infiltration contributes to the formation of Aschoff bodies.
- Activated B lymphocytes and macrophages from Aschoff bodies express large amounts of HLA class II molecules on their surfaces and may play an important role in antigen presentation to T cells that have been recognized as important effectors of chronic rheumatic valvular disease (89).
- Infiltrating T cells are cross-reactive with streptococcal M protein and cardiac myosin and laminin (molecular mimicry); CD4+ T cells have been recognized as major effectors of this process leading to chronic RHD (103–106).

- Inflammatory cytokines (increased amounts of TNF- α and interferon gamma along with decreased amounts of interleukin-4) appear to be important in persistence and progression of rheumatic valvular lesions in a susceptible host.
- Through a process called epitope spreading, T cells may respond to other cardiac alpha-helical proteins, including tropomyosin and vimentin (89,90,107–109) (Fig. 60.3).

Natural History

The prognosis and natural history of rheumatic carditis and RHD are strongly influenced by both the severity of the initial carditis and RF recurrences (110–114). Mild carditis without recurrences is much more likely to show resolution than severe initial carditis and/or cases with recurrent episodes of RF. Only 30% to 40% of patients with acute mitral regurgitation have a persistent murmur at follow-up, with most of the clinical improvement occurring in the first 6 months after the acute illness. Patients with more severe carditis (heart failure and/or cardiomegaly) are more likely to have persistent RHD, and aortic regurgitation is less likely to disappear than mitral regurgitation (115–117). The proportion of patients with RF who develop chronic RHD has decreased from 60% to 90% during the prepenicillin era to 35% to 65% (110–112,118,119). Age and gender also influence prognosis, as acute rheumatic cardiac involvement resolves more frequently in boys (111,112), and children presenting with RF before age 5 years have more severe cardiac involvement and more commonly have persistent chronic RHD (38,39).

PATHOLOGY

The pathologic changes that occur with RF are characterized by inflammation of connective tissue in the heart, joints, and subcutaneous tissues. The pathologic changes in rheumatic carditis are primarily perivascular and interstitial, without evidence of myocyte necrosis. Two phases have been described. The “exudative” phase occurs in the first 2 to 3 weeks after disease onset and is characterized by interstitial edema, cellular infiltration (T cells, B cells, and macrophages), fragmentation of collagen, and scattered deposition of fibrinoid (eosinophilic granular material). During the second “proliferative” or “granulomatous” phase, which lasts for months to years (120), the Aschoff nodule, considered pathognomonic for, and the morphologic hallmark of, RHD may be found in the endocardium, subendocardium, or myocardial interstitium (121). The Aschoff nodule is a perivascular aggregation characterized by a central area of fibrinoid change (altered collagen) surrounded by or infiltrated by large multinucleated (“owl eye”) cells. These Aschoff bodies, which are not seen in the hearts of patients dying within the first week after onset of RF, may be seen years after initial illness and do not correlate with disease activity (120,122). Cells in Aschoff bodies located underneath activated valvular endothelium appear to play an important role in antigen presentation to infiltrating T cells, which have been recognized as critical in the evolution of chronic RHD (89) (see “Immunopathogenesis” above).

Pericarditis

Grossly, the pericardial surface may have a white, fibrinous, stringy to shaggy exudate; all cases show lymphocytic and mononuclear infiltration of the pericardium. Aschoff nodules may be present in pericardium. Pericarditis heals with no significant adhesions, and constrictive pericarditis rarely occurs.

Figure 60.3. Immunopathogenesis of RF and RHD. (1) and (2) Rheumatogenic group A streptococcal (GAS) pharyngitis. (3) Cross-reactive antigen on GAS. (4) Molecular mimicry between GAS antigens and human host tissue is believed to be the basis of pathogen–host cross-reactivity, best documented with α -helical cardiac proteins such as myosin, laminin, and vimentin. (5) Vascular cell adhesion molecule 1 (VCAM-1) is upregulated at the valve and aids in recruitment and infiltration of T cells. (6) Inflammation leads to neovascularization, which allows further recruitment of T cells, leading to granulomatous inflammation and the establishment of chronic RHD. (Adapted from Steer AC and Carapetis JR. Acute Rheumatic Fever and Rheumatic Heart Disease in Indigenous Populations. *Pediatr Clin N Am* 2009;56:1401–1419, with permission from Elsevier.)

Myocarditis

The ventricles and atria are often enlarged in RHD. Histologically, the myocardium may be edematous and show non-specific inflammation. However, different from other forms of myocarditis, there is usually no evidence of cell damage. Inflammatory foci consist of lymphocytes, macrophages, and other inflammatory cells. Aschoff bodies may also be seen in locations of the myocardial interstitium. Despite frequent first-degree atrioventricular (AV) block on the ECG, the conduction system shows few pathologic changes (123,124).

Endocarditis

Endocardial inflammatory changes are responsible for the valvulitis and are therefore the most clinically significant. Small, 1 to 2 mm, friable, fibrinous, verrucous vegetations may occur on the atrial surface of the mitral valve or on the ventricular side of the aortic valve at sites of valve closure (125). Associated underlying inflammation consists of histiocytes and lymphocytes.

The mitral valve leaflets may be edematous and vascularized. With time, granulation tissue may occur, with

thickening and eventually fibrosis of the valve. Similarly, chordal inflammation may be followed by granulation tissue, fibrosis, and eventually chordal fusion. These changes may result in the mitral stenosis and regurgitation seen with chronic RHD.

Macroscopically, acute rheumatic mitral valvulitis results in chordal elongation (or even rupture) with prolapse of the anterior leaflet of the mitral valve, annular dilation, altered leaflet coaptation, and mitral regurgitation (126,127). This altered coaptation most commonly results in a posterolaterally directed jet of mitral regurgitation, directed toward an area of fibrotic thickening of the posterior left atrial wall called "McCallum's patch." Aortic valve prolapse has been proposed as one of the mechanisms contributing to acute rheumatic aortic regurgitation (128).

Vasculitis

Generalized vasculitis, in particular involving the coronary arteries and the aorta, has been described (129). It resembles changes of hypersensitivity angiitis, but rarely results in tissue damage or clinical manifestations.

CLINICAL MANIFESTATIONS

Diagnosis and Evaluation

Since there is no pathognomonic test, the diagnosis of an initial episode of RF is made using the modified Jones or other diagnostic criteria. First proposed by T. Duckett Jones (130) in 1944, these criteria have undergone four revisions or modifications, the last in 1992 (131–135). Revisions and modifications have increased the specificity but decreased the sensitivity of the criteria to avoid overdiagnosis. Although this makes sense in developed countries where RF is now relatively uncommon, strict adherence to the Updated Jones Criteria in settings where RF continues to be common may result in underdiagnosis (136–138). The latest Updated Jones Criteria (Table 60.1) are intended to be used to establish the initial attack of acute RF. The diagnosis of RF requires two major or one major and two minor Jones criteria along with evidence of a preceding streptococcal infection. The major criteria are polyarthritides, carditis, chorea, a characteristic rash called erythema marginatum, and subcutaneous nodules. The frequency of major manifestations from several published series of RF cases is shown in Table 60.2. The minor criteria are fever, arthralgia, elevated acute phase reactants, and a prolonged PR interval on the electrocardiogram. Table 60.3 lists suggested testing for patients with suspected RF. Evidence of a preceding GAS infection is discussed below in the section on *Laboratory*

Testing. The latest Update allows the diagnosis of RF to be made without fulfilling the above criteria in three circumstances: (a) patients who present with isolated chorea, (b) patients who present with indolent or insidious onset carditis (detected months to years after the acute illness), or (c) patients with a prior history of RF/RHD (133). While the Jones criteria may be used to diagnose a recurrent episode of RF in patients without RHD, diagnosing a recurrence may be difficult in the patient with existing RHD. In such cases, it is often difficult to differentiate acute carditis from progression and evolution of existing RHD. Such a distinction is important for at least two reasons: (a) cardiac changes related to an acute recurrence are likely to evolve over a shorter time period than chronic RHD and (b) some believe that steroids may be beneficial and even lifesaving in patients with severe, active carditis. On the other hand, steroids are of no therapeutic value in patients with chronic rheumatic valvular disease, and might delay more appropriate treatment. To address the diagnostic difficulty of this important group of patients, the World Health Organization has published guidelines for the diagnosis of recurrences: (a) a recurrent attack of RF in a patient without RHD requires fulfillment of the Jones criteria (two major or one major with two minor criteria, plus evidence of a preceding streptococcal infection) and (b) a recurrent attack of RF in a patient with underlying RHD requires two minor criteria and evidence of a preceding streptococcal infection (7) (Table 60.1).

TABLE 60.1 Diagnostic Criteria for Rheumatic Fever

Major Criteria	Minor Criteria
Carditis	Fever
Chorea	Arthralgia
Polyarthritides	Elevated acute-phase reactants
Erythema marginatum	Erythrocyte sedimentation rate
Subcutaneous nodules	C-reactive protein
	Prolonged PR interval (ECG)
Supporting evidence of antecedent group A streptococcal pharyngeal infection	
Positive throat culture or rapid streptococcal test	
Elevated or rising streptococcal antibody titer	
Criteria for diagnosis of:	
Primary episode of RF	Two major <i>or</i> one major plus two minor <i>plus</i> evidence of preceding streptococcal infection
RF recurrence in a patient	Two major <i>or</i> one major plus two minor <i>plus</i> evidence of preceding streptococcal infection
RF recurrence in a patient with RHD	Two minor <i>plus</i> evidence of preceding streptococcal infection
Special considerations	
Chorea or indolent/insidious onset carditis	No other criteria or evidence of preceding streptococcal infection needed
Modifications of diagnostic criteria (especially applicable where RF or RHD continues to be common)	- In order to improve sensitivity of criteria where there is concern for underdiagnosis
- Monoarthritides or polyarthralgia as a major criterion	- Especially when patient has received anti-inflammatory treatment
- Subclinical carditis as a major criterion	- Criteria for differentiating physiologic from pathologic valvular regurgitation

Modifications of the Jones diagnostic criteria have been published in parts of the world where the incidence of RF and prevalence of RHD remain high (Australia and New Zealand) (151,152). These modifications include (a) accepting monoarthritis or polyarthralgia as a major criterion, especially in cases where the patient has received anti-inflammatory treatment; (b) accepting echocardiographic detection of cardiac involvement (carditis) as a major diagnostic criterion, even in the absence of clinical carditis (see discussion of role of echocardiography below); (c) allowing for diagnosis of recurrent RF based on minor manifestations, especially in patients with RHD. The intent of these modifications is to improve the sensitivity of the diagnostic criteria in populations where RF and RHD are common and there is greater concern for underdiagnosis with its associated consequences. These modifications are presented in Table 60.1.

Arthritis

The latency period between GAS infection and most manifestations of RF ranges from 10 days to 5 weeks (latency between GAS infection and chorea is 1 to 6 months) (84). Of the major Jones criteria, migratory polyarthritis is most common, affecting 40% to 70% of cases (Table 60.2). The arthritis of RF classically migrates from large joint to large joint, and most commonly affects the knees, ankles, elbows, and wrists. Importantly, the presentation and evolution of the joint manifestations may be affected by administration of anti-inflammatory medications (aspirin or other nonsteroidal anti-inflammatory agents). It is noteworthy that in some parts of the world, monoarticular arthritis is a common mode of presentation (136,153). The joints affected with RF are red, swollen, and extremely tender, often with pain out of proportion to the objective findings. In some cases, the joints may be involved sequentially and simultaneously rather than in a migratory pattern, with a new joint becoming involved while a different joint is at a different phase of inflammation and resolution. Even untreated, the arthritis of RF usually resolves within 3 to 4 weeks and is not associated with residual abnormalities. Although carditis and arthritis commonly occur together, the severity of the joint and heart involvement tend to be inversely related (112). The reasons for this inverse relationship are unclear; some have speculated that joint involvement leads to earlier medical attention and initiation of anti-inflammatory treatment, thus preventing more severe cardiac involvement. Because of the different latency periods between the preceding streptococcal pharyngitis and the onset of symptoms, polyarthritis and chorea uncommonly occur simultaneously (154). The arthritis of RF typically responds to aspirin within 48 to 72 hours. In

fact, lack of clinical response and improvement within 2 to 3 days should prompt consideration of alternative diagnoses (155). It is worth noting that a small subset of patients relapses once or twice after a 6-week course of antirheumatic therapy (156,157). Unfortunately, although arthritis is the most common major manifestation of RF, it is also the least specific, and is therefore the *most common feature associated with misdiagnosis*. The Jones criteria often fail to exclude other causes of febrile polyarthritis (42), and an alternative diagnosis may be made only as more chronic findings develop (i.e., collagen vascular disease). The differential diagnosis for polyarthritis and fever is presented in Table 60.4 (158).

TABLE 60.4 Causes of Polyarthritis and Fever

Diagnoses	Confirmatory Study
Infectious arthritis	
Bacterial infections	
Septic arthritis	Synovial fluid and blood culture
Bacterial endocarditis	Blood culture
Lyme disease	Serologic studies
Mycobacterial and fungal arthritis	Culture or biopsy
Viral arthritis	Serologic studies
Postinfectious or reactive arthritis	
Enteric infection	Culture or serologic studies
Urogenital infection (Reiter syndrome)	Culture
Rheumatic fever	Clinical findings
Inflammatory bowel disease	Clinical findings
Rheumatoid arthritis and Still disease	Clinical findings
Systemic rheumatic illnesses	
Systemic vasculitis	Biopsy or angiography
Systemic lupus erythematosus	Serologic studies

Some patients develop arthritis after a streptococcal pharyngitis that differs from that typically associated with acute RF. This entity, termed *poststreptococcal reactive arthritis*, typically occurs after a shorter latent period (7 to 10 days), tends to be nonmigratory and more persistent, involves small joints or axial skeleton in some cases, and does not respond as dramatically to anti-inflammatory medications as does the typical arthritis of RF (159,160). The important implication of diagnosing poststreptococcal reactive arthritis as opposed to RF is the risk for subsequent valvular heart disease and need for antistreptococcal prophylaxis. Of particular importance is the fact that some patients thought to have poststreptococcal reactive arthritis have shown evidence of cardiac involvement (159–162). Conversely, a recent study showed no increased risk of valvular heart disease in a series of adults with poststreptococcal reactive arthritis (163). Given the uncertainty with respect to the risk of valvular heart disease for children with poststreptococcal reactive arthritis, some experts recommend that such patients receive secondary prophylaxis for up to a year after onset, but this is clearly an area of debate requiring further study. If valvular heart disease is detected, such patients should be considered as having had RF and should be treated accordingly (including secondary prophylaxis) (160,161,163–166).

Chorea

First described in the late 17th century, the association of chorea and rheumatism was not recognized until the 19th century. It is now known that the clinical manifestations of Sydenham chorea occur due to neuropathologic changes and inflammation in the basal ganglia, cerebral cortex, and the cerebellum (42,167).

Sydenham chorea occurs in approximately 10% to 30% of cases of RF (Table 60.2). The gender distribution is equal in younger children, but after age 10 years, females are more often affected, and chorea is uncommon in postpubertal males (42). Involuntary, purposeless movements, muscular incoordination and/or weakness, and emotional lability (42,43,168,169) characterize Sydenham chorea. Movements are abrupt and erratic, commonly affecting muscles of the face and extremities. Findings may include “fidgetiness,” facial grimaces, tongue movements described as resembling a “bag of worms,” halting and explosive speech, pronation of the hands when arms are extended above the head (“pronator sign”), irregular contractions of the hands when asked to squeeze an object (“milkmaid’s grip”), hyperextension of the fingers when hands are extended forward with eyes closed, (“spooning”), and clumsiness. Patients often come to attention based on deterioration in school performance, and neurobehavioral symptoms seen along with the chorea including irritability, poor attention span, lack of cooperation, and obsessive-compulsive symptoms are not uncommon. Sensory deficits do not occur. The neurologic manifestations are usually bilateral, but may be unilateral (hemichorea). The neurologic symptoms tend to decrease with rest and sedation and increase with effort or excitement. The duration of chorea is variable, ranging from 1 to 2 weeks to 2 to 3 years. The median duration is about 15 weeks, and 75% show resolution of symptoms by 6 months (7,152,170). Recurrent episodes of chorea are not uncommon (171). The differential diagnosis of chorea is presented in Table 60.5 (172).

The latency period between the streptococcal pharyngitis and the onset of chorea is longer than for arthritis or carditis, ranging from 1 to 6 months (42,173,174). As previously stated, because of this longer latency period, arthritis and chorea uncommonly occur simultaneously. Also related to the longer latency period for patients presenting with chorea,

acute phase reactants are often normal and antistreptococcal antibodies may not be elevated. When carditis and chorea are found in the same patient, it is often the chorea that prompts medical attention, at which time rheumatic cardiac involvement is detected. Although the combination of chorea and carditis is common, occurring in 47% of patients with RF in a recent series (60), the cardiac involvement tends to be relatively mild and heart failure is uncommon (44). However, rheumatic cardiac involvement in these patients may evolve and progress over time, with some patients presenting with chronic RHD years after the RF illness. Even patients with “pure” chorea are at risk, however, as 20% to 44% of such patients go on to develop chronic RHD that may eventually result in heart failure (110,154,168,175).

Neuroimaging (MRI or CT) abnormalities have been reported in some patients with Sydenham chorea (176). However, reported findings have been variable, and many patients have had normal imaging studies. Thus, neuroimaging should be reserved for atypical cases to exclude other causes of chorea. Similarly, although abnormalities have been described (177), EEG testing should be reserved for atypical cases.

In 1998, Swedo and colleagues proposed that, in some patients, childhood obsessive-compulsive symptoms and tics occur as a result of an autoimmune response to a preceding streptococcal infection, terming the entity PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections) (178,179). Because the proposed mechanism of autoimmunity related to cross-reactivity between streptococcal antigens and brain tissue is similar to the mechanism invoked for Sydenham chorea, it has been suggested that secondary prophylaxis might prevent recurrent neurologic symptoms (180,181). In some patients, it can be difficult to differentiate choreiform movements from tics (168,172). Differentiating PANDAS from Sydenham chorea is important since the treatments and prognoses are different, in particular related to the risk of chronic RHD. Patients with PANDAS may respond to plasmapheresis or intravenous gamma globulin (182). Other manifestations of RF (including carditis and RHD) have not been reported in patients with PANDAS (179). At present, there continues to be considerable debate regarding the association of streptococcal infection and neuropsychiatric disorders (PANDAS), and some consider the entity as a yet-unproven hypothesis (165,183,184).

Carditis

The manifestation of RF associated with long-term morbidity and mortality is carditis, which occurs in 30% to 70% of cases (Table 60.2). Rheumatic carditis remains the most common cause of acquired heart disease in children and young adolescents in developing countries. Despite traditionally being described as a pancarditis, the dominant and most important abnormality with acute rheumatic cardiac involvement is the *valvulitis*, specifically mitral and/or aortic regurgitation. The clinical presentation may be quite variable, ranging from the asymptomatic patient with a characteristic heart murmur to the critically ill patient presenting in heart failure. Severe carditis and heart failure occur in 13% to 64% of RF cases and represent 15% to 50% of patients with carditis (Table 60.2) (60,110,112,136,140–148). Some of the variability is likely related to the fact that some patients present only after more than one episode of RF and carditis, a scenario much more likely to be associated with significant valvular disease and heart failure. Approximately 80% of patients who develop carditis do so within the first 2 weeks of the RF illness; if no cardiac involvement is detected in the first 2 weeks, the likelihood of subsequent cardiac involvement during the acute phase is low (185). The severity of carditis and valvular regurgitation

TABLE 60.5 Differential Diagnoses of Chorea

Category	Diagnoses and Causes
Drug-related	Anticonvulsants (phenytoin, carbamazepine) Anticholinergics CNS stimulants (amphetamines) Dopamine agonists (Levodopa) Oral contraceptives
Genetic/Hereditary	Huntington disease Wilson disease Lesch-Nyhan syndrome Benign familial chorea Ataxia telangiectasia Neuroacanthocytosis Familial paroxysmal choreoathetosis Hallervorden-Spatz Disease
Endocrine/Metabolic	Hyperthyroidism Hypoparathyroidism Chorea gravidarum (pregnancy) Hypoglycemia, hyperglycemia, hypocalcemia, hypomagnesemia
Immunologic	Systemic lupus erythematosus Antiphospholipid antibody syndrome
Infectious	Viral encephalitis AIDS related Lyme disease Bacterial endocarditis
Vascular	Arteriovenous malformation Cerebrovascular accident (stroke) Cerebral hemorrhage

often decreases as the inflammation subsides. If the cardiac involvement is mild, patients may show complete resolution of cardiac findings, but patients with moderate-to-severe carditis are more likely to experience persistent and/or evolving RHD (110,112).

Mitral regurgitation, the dominant cardiac abnormality in patients with RF, occurs in approximately 95% of cases with *acute* rheumatic carditis. Both echocardiographic and surgical observations have demonstrated the mechanism of this mitral regurgitation to be a combination of annular dilatation and chordal elongation that results in abnormal coaptation, and in some cases, prolapse of the tip of the anterior mitral leaflet (Figs. 60.4 and 60.5) (186–188). Rarely, the mitral valve chordae rupture, resulting in a flail mitral leaflet and severe mitral regurgitation (168,189–191) (Fig. 60.5).

Most patients with acute mild mitral regurgitation are asymptomatic. With acute moderate-to-severe mitral regurgitation, the left ventricular myocardium may be unable to handle the significant volume overload and left heart filling pressures rise, leading to pulmonary venous congestion and pulmonary edema. Such patients usually present with features of left heart failure, including dyspnea, orthopnea, paroxysmal nocturnal dyspnea, cough, and even hemoptysis. Secondary pulmonary hypertension may develop, resulting in right ventricular dysfunction, tricuspid regurgitation, and right heart failure. Children younger than age 5 years with RF and carditis

Figure 60.4. Acute rheumatic carditis. Two-dimensional echocardiographic parasternal long-axis image showing prolapse of the tip of the anterior leaflet, resulting in a regurgitant orifice (arrow) and left heart dilation. Note also the small pericardial effusion. LA, left atrium; LV, left ventricle.

Figure 60.5. Mechanisms of anterior mitral leaflet prolapse in RHD. A: Prolapse owing to chordal elongation to anterior leaflet. B: Prolapse (flail leaflet) owing to ruptured primary chordae. C: Leaflet pseudoprolapse owing to immobile posterior leaflet, while the anterior leaflet remains at the annular plane in systole. (From Kalangos A, Beghetti M, Vala D, et al. Anterior mitral leaflet prolapse as a primary cause of pure rheumatic mitral insufficiency. *Ann Thorac Surg* 2000;69:755–761, with permission from Elsevier.)

may present more insidiously with fever, decreased appetite, lethargy, fatigue, and vague pains. Because of these subtle and nonspecific symptoms, the diagnosis may be delayed, and presentation with heart failure is more common than in older children (38,39). On physical examination, tachycardia is often one of the earliest signs of carditis. Significant mitral regurgitation may result in increased precordial activity, tachypnea, and increased work of breathing. A high-pitched, regurgitant, holosystolic murmur of mitral regurgitation is heard best at the apex, usually radiating into the left axilla. This murmur is best heard at end-expiration with the patient in the left lateral decubitus position. It is noteworthy that acute, severe mitral regurgitation may be present despite a fairly soft systolic murmur (192). Although mitral stenosis does not occur with the initial episode of acute RF and carditis, a low-pitched mid-diastolic apical murmur may be heard in the setting of significant mitral regurgitation due to increased diastolic flow across the mitral valve (Carey Coombs murmur) (193). Contrary to some reports (133), this murmur is never heard in isolation.

Aortic regurgitation occurs in approximately 20% to 25% of patients with acute rheumatic carditis, usually in combination with mitral regurgitation. Isolated aortic regurgitation occurs in approximately 5% of patients with acute rheumatic carditis (60,144). Leaflet prolapse has been reported to be one of the mechanisms of this acute valvular dysfunction (128,188). Patients with *acute* mild aortic regurgitation are usually asymptomatic. Moderate-to-severe acute aortic regurgitation is less well tolerated, and may result in heart failure. The large regurgitant volume imposed on a left ventricle that has not had time to compensate for the significant volume load results in decreased forward stroke volume in conjunction with significant elevation of ventricular end-diastolic pressure, leading to a combination of low cardiac output and pulmonary edema (194). Patients with acute severe aortic regurgitation are tachycardic and tachypneic. Unlike the clinical examination found with significant chronic aortic regurgitation, the pulse pressure is often narrow and the pulses are not increased or bounding. Precordial activity is often increased, but the apical impulse may not be significantly displaced. On auscultation, the decrescendo diastolic murmur is softer, lower-pitched, and shorter than the murmur heard with chronic regurgitation, and thus, this

murmur can be easily missed, especially with the tachycardia commonly present during the acute phase of the illness. A short systolic ejection murmur may be heard over the left ventricular outflow tract due to increased flow. A low-pitched mid-to-late diastolic rumbling murmur with presystolic accentuation may be heard at the apex, even with a nonstenotic mitral valve. If present, this “Austin Flint” murmur is softer and shorter in the setting of acute as compared to chronic severe aortic regurgitation. Acute rheumatic aortic regurgitation is less likely than mitral regurgitation to disappear with resolution of the acute inflammatory stage of the illness (110,112,115).

Pericarditis occurs in approximately 4% to 11% of patients with acute rheumatic carditis (60,143–145). When it occurs, it is invariably associated with significant left-sided valvular disease. In the absence of significant mitral and/or aortic regurgitation, pericarditis is unlikely related to RF, and other etiologies should be considered. Clinically, patients may have the typical positional chest and shoulder pain seen with pericarditis. On auscultation, a friction rub may obscure the murmur(s) of valvular regurgitation. In other cases, the friction rub may be evanescent and intermittent. Echocardiography allows detection and semiquantitation of pericardial effusions and evaluation of valvular function. Unlike pericarditis associated with other etiologies, pericardial tamponade (190) and constrictive pericarditis (195) rarely occur.

Although acute RHD has long been considered a pancarditis (173,196), the clinically important abnormalities are related to valvular pathology and regurgitation rather than myocarditis and myocardial dysfunction (197). Biopsy and autopsy pathologic specimens show evidence of myocardial involvement (including the characteristic Aschoff bodies), but unlike other types of myocarditis, myocyte necrosis associated with lymphocytic infiltration does not occur (198) and troponin I levels are not elevated (199,200). Further, although there may be evidence of subtle abnormalities of contractility (201), several studies have shown that left ventricular ejection phase indices (shortening and ejection fraction) are normal in these patients (197,202,203). Thus, it is important to emphasize that *heart failure does not occur in acute or chronic RHD in the absence of significant valvular regurgitation* (26,187,197,204).

Erythema Marginatum

The rash of erythema marginatum is a relatively uncommon finding, occurring in <5% of patients with RF (Table 60.2) (60,205,206). The rash appears as a bright pink macule or papule that spreads with serpiginous borders and central clearing. The lesions are painless, not pruritic, blanch on pressure, and are usually macular rather than papular. Most commonly seen on the trunk or proximal extremities, the rash is evanescent and the lesions may change in appearance rapidly. A hot bath or shower may bring out or accentuate the rash. Because of its evanescent nature and lack of associated symptoms, it may be easily missed. Although typically seen early in the course of RF, persistence or recurrence for months or even years has been described. Erythema marginatum is usually associated with carditis, and almost never occurs as the sole major Jones criterion (42,206,207).

Subcutaneous Nodules

Subcutaneous nodules are relatively uncommon in RF, reported in 0 to 10% of cases (Table 60.2). They are not pathognomonic of RF, and may occur with systemic lupus or rheumatoid arthritis. The nodules are 0.5 to 2.0 cm in diameter, round, firm, freely movable, nontender, and with no evidence of inflammation. They tend to occur in crops over extensor surfaces of joints or bony prominences of the elbows, wrists, knees, ankles, scalp, and spinous processes of the back. These nodules persist for a few days to as long as 1 to 2 weeks and are not evanescent. However, because they may be small and are not associated with symptoms, they may be easily missed. Similar to erythema marginatum, subcutaneous nodules are almost always associated with carditis and rarely occur as the sole major Jones manifestation (42,207,208).

Minor Criteria and Other Clinical Manifestations

The minor Jones manifestations are less specific than the major criteria and include fever, arthralgia, elevated acute phase reactants, and first-degree AV block (prolonged PR interval) on ECG (Table 60.1). Fever occurs at the onset of the RF illness in most cases, with temperatures usually ranging from 101°F to 104°F. Some patients have a history of fever, but are afebrile at the time of initial clinical evaluation. In particular, patients presenting with chorea are usually afebrile. Arthralgia, which is joint pain without objective findings, usually involves the large joints. The pain may be variable, ranging from mild to very severe, and may be migratory in nature. Arthralgia cannot be used as a minor criterion when polyarthritis is used as a major diagnostic criterion. Laboratory and ECG abnormalities are discussed in the following two sections.

Clinical manifestations seen in patients with RF not included in the Updated Jones Criteria include epistaxis and abdominal pain (typically epigastric or periumbilical), which occur in about 5% of cases, and may occur hours to days before any of the major manifestations (44). Both were minor manifestations in the original Jones criteria (130), but were removed because of lack of specificity. Other nonspecific features include anorexia, malaise, anemia, and a family history of RF or RHD.

Laboratory Testing

There is no definitive diagnostic test for RF. Suggested testing for patients with suspected RF are listed in Table 60.3. With few exceptions (chorea or insidious onset carditis), in addition to the major and/or minor Jones criteria, diagnosis of acute RF requires evidence of a preceding GAS infection. Although

a positive throat culture or rapid antigen test is accepted as such evidence, the rate of recovery of GAS from the pharynx of patient with RF is low. Moreover, some patients may have a positive culture or test due to a carrier state rather than true infection. Thus, elevated or rising antibody titers are more reliable evidence of a preceding GAS infection. The titers most commonly measured are antistreptolysin O (ASO) and antideoxyribonuclease B (anti-DNase b). When a single antibody is measured, 80% to 85% of patients with RF will have an elevated titer. When two titers are measured, well over 90% of patients with RF will have elevation of at least one titer (209,210). The ASO titer is often measured first; if it is not elevated, the anti-DNase b may be measured. ASO titers rise approximately 1 week and peak 3 to 6 weeks following infection. Anti-DNase b titer rises 1 to 2 weeks and peaks 6 to 8 weeks following infection (165). It should be emphasized that antistreptococcal antibody titers must be interpreted in the setting of clinical manifestations; elevated and/or rising titers only provide evidence of a preceding streptococcal infection, not RF.

Elevated acute phase reactants such as C-reactive protein and erythrocyte sedimentation rate are minor Jones criteria (133), and are invariably seen in patients with RF and arthritis and/or acute carditis. Thus, measurement of acute phase reactants is useful in differentiating acute carditis from indolent RHD (presenting after acute inflammation has resolved) and may guide treatment with anti-inflammatory agents (211). The degree of inflammation at presentation is of prognostic importance since acute carditis is more likely than chronic RHD to resolve over time. As previously stated, patients with chorea often show no elevation of acute phase reactants.

Electrocardiography

Patients with suspected RF should have an ECG since conduction abnormalities are not uncommon. Although first-degree AV block is a minor Jones criterion, it should be noted that a prolonged PR interval occurs in up to one-third of patients who have GAS infections, regardless of whether they develop RF (207). Though useful as a minor Jones criterion in support of the diagnosis of RF, first-degree AV block is not associated with either the severity of the initial cardiac involvement or a greater likelihood of developing chronic RHD (112,208). Less commonly, the ECG may reveal more advanced AV block or other abnormalities (212–214).

Echocardiography

Two-dimensional and Doppler echocardiography is central to the diagnosis and management of valvular disease and should be performed in all patients with acute or chronic RHD. Echocardiography is valuable for evaluating the mechanism and severity of valvular regurgitation and/or stenosis, leaflet and chordal morphology, annular size, chamber sizes and function, pericardial effusion, and pulmonary artery pressures (128,194,202,215,216). Echocardiography is also valuable in differentiating RHD from other entities such as innocent murmurs, congenital heart disease, or myocarditis, and thus helps avoid overdiagnosis of RF in up to 20% of cases (217–219). The mitral valve often appears normal on 2-D echocardiographic imaging of patients with mild acute rheumatic mitral regurgitation. Others have described focal nodular thickening of valve leaflets (thought to represent the verrucae seen at autopsy of patients who died with acute carditis) that disappears on follow-up (202). In cases severe enough to result in heart failure, chordal elongation and annular dilation may be seen, often resulting in anterior leaflet prolapse (Figs. 60.4 and 60.5) (186,197). The mitral valve prolapse seen in RF patients

differs from the redundant, myxomatous mitral valve and prolapse seen with Barlow syndrome. In rheumatic carditis, only the coapting portion of the anterior leaflet prolapses, and there is no billowing of the medial portion or body of the leaflet (220). This results in abnormal leaflet coaptation, a regurgitant orifice, and a jet of mitral regurgitation that is typically posterolaterally directed (221,222). Rarely, chordal rupture results in a flail leaflet and severe mitral incompetence (Fig. 60.5) (189–191,223,224). In the setting of acute rheumatic aortic regurgitation, the aortic valve may appear normal or show mild prolapse by 2-D echocardiographic imaging. The severity of mitral and/or aortic regurgitation should be evaluated using a combination of methods (216).

Echocardiography may detect mitral and/or aortic regurgitation in patients with RF who have no evidence of clinical carditis on physical examination (no murmur). Although a single report did not find evidence of cardiac involvement in the absence of clinical findings (202), there are now several reports of such subclinical or “silent” cardiac involvement in patients with either isolated polyarthritis or “pure” chorea at the time of presentation (219,222,225,226). The fact that some patients with RF have such subclinical evidence of cardiac involvement is not surprising. It is well known that the severity of cardiac involvement ranges from very mild to severe. Even in the “golden era” of clinical auscultation of the 1950s, some patients with no clinical carditis at presentation with RF (no murmur) were found to have RHD on follow-up (110,112). In the current era with diminished auscultatory skills (227), this is likely to be an even more frequent occurrence. Further support for the existence of subclinical echocardiographic evidence of cardiac involvement comes from the fact that some series have described a subset of patients with initially “silent” subclinical evidence of carditis who subsequently developed murmurs of mitral and/or aortic regurgitation (226,228). Indirect evidence in support of “silent” subclinical carditis comes from natural history studies. Many adults who present with chronic RHD cannot recall having a previous RF-like illness, suggesting very mild or subclinical cardiac involvement with acute RF illness (229). As many as 20% to 44%

of patients with “pure” chorea have been reported to develop chronic RHD (154,168,175,229). Despite evidence in support of these findings, there has appropriately been concern over creating “iatrogenic” disease since a significant percentage of normal individuals have very small amounts of “physiologic,” Doppler-detected valvular regurgitation (mostly tricuspid, pulmonary, and mitral), especially with advances in ultrasound technology. To avoid labeling such normal findings as abnormal, strict criteria should be used to differentiate pathologic mitral and aortic regurgitation from the Doppler signals seen in normal individuals. The World Health Organization recommends the following criteria to differentiate pathologic from physiologic mitral and aortic regurgitation: (a) color jet >1 cm in length, (b) color jet evident in at least two imaging planes, (c) color jet mosaic with peak velocity >2.5 m/s, and (d) Doppler signal holosystolic for mitral regurgitation and holodiastolic for aortic regurgitation (Fig. 60.6) (7). Although echocardiography may not be available in some of the developing countries where RF is most common (230), the World Health Organization recognizes its usefulness and recommends that echocardiography be performed in the evaluation of patients with RF if facilities are available. Furthermore, the World Health Organization recommends that silent but significant mitral and/or aortic regurgitation be considered *probable* RHD and that such patients be given secondary prophylaxis and followed long-term for evolution of heart disease (7). Echocardiography should also be performed in the evaluation and follow-up of patients with established chronic RHD. The role of echocardiography in *screening* for RHD is discussed below in the section on *Secondary Prophylaxis*.

Cardiac Catheterization

Catheterization and angiography are rarely necessary for the management of patients with acute rheumatic valvular disease, including those who ultimately require surgery. Endomyocardial biopsy does not add to the diagnosis or management (198). Catheterization should be reserved for those in whom

Figure 60.6. Silent rheumatic mitral regurgitation. Two-dimensional echocardiographic parasternal long-axis (A) and apical four-chamber (B) images showing a posterolaterally directed jet of mitral regurgitation extending into the left atrium well beyond the mitral valve leaflets.

symptoms, clinical findings, and noninvasive imaging are discrepant, when measurement of pulmonary artery pressure and pulmonary vascular resistance is important in decision-making, and when balloon valvuloplasty for mitral stenosis is being contemplated (231). In adults with RHD, catheterization and angiography may be indicated to evaluate the coronary vascular bed prior to surgical intervention for valvular RHD (194).

Other Cardiac Imaging

The chest radiograph may be valuable in assessing patients with acute or chronic RHD to evaluate cardiac size, configuration, and pulmonary venous markings. The cardiac silhouette may be enlarged due to valvular regurgitation and chamber enlargement and/or due to an associated pericardial effusion.

Although studies have shown white blood cell scanning (232) and antimyosin scintigraphy (233) to detect cardiac involvement in some patients with RF, there are insufficient data to support their routine use in the evaluation of patients with RF.

CHRONIC RHEUMATIC HEART DISEASE

Mitral Regurgitation

Chronic mitral regurgitation is the most common form of RHD in children and young adults (111,113,117), while mitral stenosis is increasingly common in patients in the fourth to sixth decades of life (85). In contrast to the chordal elongation and annular dilation that occur with acute rheumatic mitral valvulitis and regurgitation, leaflet shortening, rigidity, deformation, and retraction, often associated with chordal fusion and shortening, result in abnormal leaflet coaptation and chronic rheumatic mitral regurgitation. In addition, left ventricular dilation may alter the position and orientation of the mitral valve papillary muscles, further impairing leaflet coaptation and resulting in a larger regurgitant orifice and regurgitant volume (234). Chronic mitral regurgitation results in compensatory dilation of the left ventricle, allowing for an increased total stroke volume that maintains forward flow. The combination of compensatory dilation of the left ventricle and the left atrium initially prevents a rise in left ventricular filling, left atrial, and pulmonary venous pressures. Although patients may remain asymptomatic for years with this compensation, the mitral regurgitation may progress over time (235). Severe chronic mitral regurgitation may eventually result in ventricular dysfunction with decreased ejection fraction, elevated end-systolic volume, and elevated left heart filling pressures. Symptoms, most commonly exertional dyspnea or decreased exercise tolerance, may develop prior to, or with the onset of, ventricular dysfunction (194,236,237).

In the setting of chronic mitral regurgitation, precordial activity is increased and the apical impulse is displaced because of ventricular dilation. The first heart sound is often softer than normal, and the second heart sound may be widely split due to shortened left ventricular ejection and earlier aortic valve closure. If there is associated pulmonary hypertension, the pulmonary component of the second heart sound (P2) may be increased. A regurgitant systolic murmur is best heard at the apex; more subtle mitral regurgitant murmurs may be heard at end-expiration with the patient in the left lateral decubitus position. When the regurgitant jet is posterolaterally directed, the murmur radiates to the left axilla. Medially directed jets may result in radiation of the murmur toward the base of the heart. For chronic mitral regurgitation, the intensity of the murmur correlates with the severity of regurgitation. When

the regurgitant volume is significant, an apical diastolic flow rumble may be heard in the absence of mitral stenosis.

The chest radiograph is usually normal in patients with mild mitral regurgitation. With moderate-to-severe mitral regurgitation, left atrial and left ventricular enlargement occur, resulting in a straight left heart border and cardiomegaly. Elevation of the left mainstem bronchus may be evident. Pulmonary venous congestion and interstitial edema may be evident with severe, decompensated mitral regurgitation and heart failure.

The ECG in patients with chronic RHD is most important for demonstrating the rhythm. The ECG is normal in patients with mild mitral regurgitation but may show left atrial enlargement and/or left ventricular hypertrophy in patients with moderate-to-severe mitral valve incompetence. ECG changes do not correlate with the severity of the mitral regurgitation. Right ventricular hypertrophy may be evident in cases with secondary pulmonary hypertension. Atrial fibrillation is rare in children, but may be seen in adults with chronic rheumatic mitral valve disease.

On echocardiography, the mitral valve leaflets are thickened and often echogenic with variably decreased mobility. Leaflet excursion may be decreased during both diastole and systole. Abnormal leaflet coaptation results in a regurgitant orifice. In some cases, the anterior leaflet tip prolapse seen with acute carditis persists as chronic rheumatic mitral regurgitation. In other cases, the combination of a retracted, relatively immobile posterior (mural) leaflet with a more mobile anterior leaflet can give the impression of anterior prolapse even though the free edge of the anterior leaflet remains in the annular plane during systole. Such a combination, termed "pseudoprolapse," also results in poor leaflet coaptation and significant regurgitation (Fig. 60.5) (191).

Aortic Regurgitation

Chronic rheumatic aortic regurgitation occurs due to leaflet thickening, fibrosis, and leaflet contracture, resulting in abnormal leaflet coaptation and a regurgitant orifice. This regurgitation leads to both volume and pressure overload of the left ventricle (194). During a compensatory phase, ventricular dilation occurs to maintain forward stroke volume and cardiac output, and ejection fraction remains normal. Similar to patients with chronic mitral regurgitation, patients with chronic severe aortic regurgitation may remain asymptomatic for years (194,238). Over time, decompensation may occur, resulting in decreased left ventricular function and/or symptoms, most commonly dyspnea on exertion or decreased exercise tolerance.

On examination, significant chronic aortic regurgitation results in a wide pulse pressure (elevated systolic and low diastolic pressures) and bounding pulses. Precordial activity is increased, and the apical impulse is displaced laterally due to the dilated left ventricle. The typical diastolic murmur of aortic regurgitation is relatively high-pitched, decrescendo, and heard best along the left sternal border with the patient leaning forward at end-expiration. The duration of the murmur rather than the intensity correlates with the severity of regurgitation. A short systolic ejection murmur may be heard at the mid-left or upper right sternal border from increased flow across the left ventricular outflow tract or associated aortic valve stenosis. In patients with moderate-to-severe aortic regurgitation, a low-pitched mid-to-late diastolic rumbling murmur may be audible at the apex in the absence of organic mitral stenosis ("Austin Flint" murmur).

The chest radiograph is usually normal in mild aortic regurgitation and shows progressive cardiomegaly with increasing severity of aortic valve incompetence. With significant aortic regurgitation, a dilated ascending aorta may be evident.

The ECG is usually normal in cases with mild aortic regurgitation, but may show left ventricular hypertrophy with moderate-to-severe aortic valve incompetence.

On echocardiography, the aortic valve leaflets may show thickening, retraction, and variable commissural fusion. The severity of the aortic regurgitation should be assessed (216) along with documentation of associated lesions, in particular mitral valve stenosis or regurgitation. Left ventricular size and function should be assessed in all patients with aortic regurgitation.

Mitral Stenosis

RF resulting in chronic RHD is the most common cause of mitral stenosis. Mitral stenosis does not occur with acute initial carditis. In industrialized countries, the interval between the occurrence of RF and the onset of symptoms from mitral stenosis is usually 15 to 40 years, resulting in presentation in the third to fifth decades of life (85). In contrast, symptomatic rheumatic mitral stenosis may occur as early as the second decade of life in children from developing countries of the world (27,29,33). While both greater severity of cardiac involvement with the initial illness and multiple recurrences of RF likely contribute to the development of this more aggressive form of chronic RHD, it is also possible that the disease process itself is different in developing countries of the world (27). Mitral stenosis may occur as the dominant lesion, with insignificant amounts of associated regurgitation ("pure" mitral stenosis), or in combination with significant mitral regurgitation (239). Women are more likely than men to develop rheumatic mitral stenosis (66,111).

A combination of leaflet thickening, fusion of commissures, cusps and chordae, and chordal shortening result in a funnel-shaped, stenotic mitral valve orifice. Over time, the valve may calcify, further impairing leaflet mobility. The process is usually continuous and slowly progressive (at least in industrialized countries), eventually resulting in left ventricular inflow obstruction and a diastolic gradient between the left atrium and ventricle. Patients with mild stenosis are usually minimally symptomatic. With increasing stenosis, however, left atrial and pulmonary venous pressures rise, leading to pulmonary venous congestion and, eventually, pulmonary hypertension. Many patients accommodate their lifestyle to the gradual development of symptoms and are unaware of their significant functional limitations. The most common early symptoms are due to decreased cardiac output and include fatigue and decreased exercise tolerance. Dyspnea on exertion, cough, wheezing, shortness of breath, orthopnea, and paroxysmal nocturnal dyspnea may develop as the patient's condition worsens and pulmonary edema develops. Although uncommon in children, atrial fibrillation may result in atrial thrombi and systemic embolization. With severe mitral inflow obstruction and pulmonary hypertension, hemoptysis and signs of right heart failure, including edema and abdominal distension, may be evident.

On examination, findings depend on the severity of the stenosis and associated lesions. Precordial activity may be abnormal with a tapping, palpable first heart sound, but the apical impulse is not usually displaced unless there is associated mitral and/or aortic regurgitation. Prominent a-waves may be visible in the jugular venous pulsations. On auscultation, the characteristic findings of mitral stenosis are an increased S1, an early diastolic opening snap, and a low-pitched, rumbling diastolic murmur best heard at the apex with the patient in a left lateral decubitus position. The duration rather than the intensity of the murmur correlates with the severity of obstruction. In addition, the interval between S1 and the opening snap decreases with increased stenosis (elevated left atrial pressure

results in earlier opening snap). For patients in sinus rhythm, late diastolic or presystolic accentuation of the murmur may be audible due to the increased gradient associated with atrial contraction. With severe stenosis and a rigid, calcified mitral valve, the opening snap and S1 may be inaudible. When secondary pulmonary hypertension occurs, P2 increases, and a right ventricular impulse or lift may be noted. Tricuspid regurgitation due to a combination of rheumatic tricuspid valve involvement and pulmonary hypertension may become clinically evident with a regurgitant systolic murmur at the lower left sternal border, a pulsatile liver, and abnormal jugular venous pulsations.

Typically normal in patients with mild mitral stenosis, the chest radiograph may show left atrial enlargement in patients with more significant mitral valve obstruction. The left ventricle is not enlarged unless there is associated mitral or aortic regurgitation. The pulmonary artery and right ventricle may enlarge when there is associated pulmonary hypertension.

The ECG is most important for determining the rhythm, since atrial fibrillation is an important complication of significant mitral stenosis. The ECG is normal if the mitral stenosis is mild, but may show left atrial enlargement with significant stenosis. Right axis deviation or right ventricular hypertrophy may be evident if there is secondary pulmonary hypertension. It is notable that ECG findings do not correlate with the severity of the mitral stenosis.

On echocardiography, patients with rheumatic mitral stenosis have valvar and subvalvar changes including thickened echo-dense leaflets, commissural fusion, abnormal diastolic leaflet excursion (doming), and calcification; fusion, shortening, fibrosis, and calcification of the mitral valve chordae. Mitral regurgitation and stenosis may coexist in such patients. The leaflets begin to open in diastole, and although the body of the leaflets may continue to move, commissural fusion limits the excursion of the leaflet tips resulting in the characteristic "bent-knee" or "hockey-stick" appearance of the anterior leaflet typical of rheumatic mitral stenosis (Fig. 60.7). The posterior leaflet may show very limited excursion and appear "frozen." Over time, the valve may calcify, first at the leaflet tips and later extending toward the annulus. With increased thickness and calcification, the leaflets become less pliable and motion is further restricted. Although the left atrium is dilated with significant stenosis, the left ventricle is normal in size unless there is concomitant mitral and/or aortic regurgitation. The severity of the mitral stenosis may be assessed from Doppler peak and mean gradients, planimetry of the valve opening, pressure half-time, or proximal Doppler flow convergence (240). Leaflet mobility, thickening, calcification, and subvalvular thickening have been shown to be useful echocardiographic features for identifying patients who are good candidates for balloon valvotomy of mitral stenosis (241–243). When possible, pulmonary artery pressures should be estimated from the tricuspid and pulmonary regurgitation velocities since pulmonary hypertension may occur with more severe degrees of mitral stenosis. Both right and left ventricular function should be assessed in all patients with mitral stenosis. When available, 3-D echocardiography allows assessment of both valve area and candidacy for balloon valvotomy (244).

Exercise or other forms of stress testing may be of value in evaluating patients with equivocal symptoms or in whom the symptoms are greater than would be expected based on the resting echocardiogram. In some patients, the transmitral gradient and pulmonary artery pressure rise significantly with exercise. Asymptomatic patients with significant mitral stenosis who show poor exercise capacity or a significant rise in estimated pulmonary artery systolic pressure (>60 mm Hg) with stress testing should be considered for transcatheter or surgical intervention (245).

Figure 60.7. Chronic rheumatic mitral stenosis. A: Two-dimensional echocardiographic parasternal long-axis image demonstrating bent-knee or hockey-stick configuration to thickened anterior mitral valve leaflet (arrow). B: Apical four-chamber image showing thickened, echogenic leaflets and restricted diastolic opening (arrow); LA, left atrium; LV, left ventricle.

Aortic Stenosis

Like mitral stenosis, aortic valve stenosis is a form of chronic rather than acute RHD and occurs 20 to 40 years after the acute illness as adhesions, leaflet thickening, fibrosis, commissural fusion, and calcific nodules may develop over time. These changes lead to decreased leaflet mobility, decreased aortic orifice size, and obstruction to flow. Rheumatic aortic stenosis and regurgitation often occur concurrently, usually along with rheumatic mitral valve disease. The increase in stenosis is gradual, allowing for ventricular compensation and the absence of symptoms. With time, compensation fails and symptoms develop (including angina, syncope, dyspnea on exertion and heart failure), most often in the fifth to sixth decades of life (246).

With severe stenosis, the arterial pulse may be decreased, with a slow rate of rise. Conversely, if there is associated aortic regurgitation, the pulses may be increased. Similar to congenital aortic valve stenosis, a thrill may be palpable at the upper right sternal border or in the suprasternal notch. A systolic ejection murmur is heard best at the upper right sternal border, but in contrast to congenital aortic valve disease, an ejection click is uncommon with rheumatic aortic valve stenosis. A decrescendo diastolic murmur may be audible if there is associated aortic regurgitation.

On echocardiography, 2-D imaging often demonstrates thickened leaflets with variable degrees of commissural fusion and leaflet retraction, responsible for the variable degrees and combinations of aortic regurgitation and stenosis. Doming of the leaflets, increased echogenicity from calcification, and restricted motion develop as the stenosis progresses. The severity of aortic stenosis can be evaluated by measuring peak instantaneous and mean Doppler gradients or aortic valve area using the continuity equation. Left ventricular dimensions, volumes, wall thicknesses, mass, and function should be measured as they importantly contribute to clinical management decisions. The mitral valve should be carefully evaluated

in all patients with chronic rheumatic aortic valve disease since coexistent mitral valve involvement is common.

Right Heart Involvement

In patients with chronic RHD, tricuspid and/or pulmonary valve involvement may be functional (related to the pulmonary hypertension that may occur with significant left heart disease) or organic (chronic rheumatic changes) (247). The tricuspid valve is affected more often than the pulmonary valve by the rheumatic process, but clinically significant involvement of either valve is uncommon. Rheumatic tricuspid valve disease (stenosis and/or regurgitation) virtually always occurs with significant mitral or aortic valve disease. Although histologic evidence of rheumatic tricuspid valve involvement may be detectable in up to 15% to 40% of patients with RHD (247–250), significant tricuspid valve disease is detectable by echocardiography in only 7% to 9% (247,251) and is clinically apparent in 3% to 5% of patients with RHD (250,252). Rheumatic tricuspid stenosis results from a combination of leaflet thickening, fusion of commissures and chordae, and chordal contraction and shortening that limits diastolic leaflet motion and creates a stenotic orifice. Leaflet contraction and annular dilation may affect leaflet coaptation and result in tricuspid regurgitation.

In some cases, it may be difficult to determine whether a patient's symptoms (fatigue, exercise intolerance, peripheral edema) are from tricuspid stenosis or mitral stenosis. Features typical of tricuspid stenosis include prominent jugular venous a-wave pulsations, an opening snap, and a low-pitched diastolic rumbling murmur at the lower left or right sternal border as opposed to the apex where mitral stenosis is characteristically heard (253). Right heart failure with peripheral edema, hepatomegaly, right upper quadrant tenderness, and ascites may be evident in advanced disease.

On echocardiography, patients with tricuspid regurgitation may have right ventricular enlargement and/or hypertrophy,

right atrial enlargement, and tricuspid annular dilation. Similar to the rheumatic stenotic mitral valve, thickened leaflets with doming and decreased motion are characteristic findings in rheumatic tricuspid stenosis (254,255). Doppler allows estimation of the severity of both the tricuspid regurgitation (216,256,257) and stenosis (254).

Although uncommonly involved in either acute or chronic RHD, the pulmonary valve may show evidence of rheumatic involvement after the Ross procedure (pulmonary autograft replacement of the aortic valve) (258), leading to significant neo-aortic regurgitation and, in some cases, the need for subsequent aortic valve replacement (259,260).

TREATMENT

The medical management of acute rheumatic carditis has not changed substantially since the mid-1950s. Treatment remains largely supportive and directed at preventing recurrences, complications, and deciding on the optimal time for intervention for chronic valvular disease. Although anti-inflammatory treatment is widely accepted as an integral part of the treatment regimen of acute RF and provides symptomatic relief, there is little evidence that such treatment alters the natural history of RHD (33,111,261). Although quite variable, the duration of an untreated case of RF is approximately 3 months, with the course for patients with carditis varying from that of complete recovery with no sequelae to intractable heart failure requiring surgical intervention. The various forms of treatment of acute rheumatic carditis and chronic RHD are summarized in Tables 60.6 and 60.7.

TABLE 60.6 Treatment of Acute Carditis

- General management
 - Restricted activity: some recommend bed/chair rest for approximately 4–6 wk for carditis
 - Primary prophylaxis (see Table 60.8)
 - Initiate secondary prophylaxis (see Table 60.9)
- Anti-inflammatory therapy (see text for discussion)
 - Mild-to-moderate carditis
 - Aspirin: 80–100 mg/kg/d in four divided doses for children (target salicylate levels 20–30 mg/dL)
 - Aspirin: 4–8 g/d in adolescents and adults (target salicylate levels 20–30 mg/dL)
- Severe carditis
 - Initial steroids (prednisone 2 mg/kg/d) for approximately 2 wk, then taper
 - Begin aspirin approximately 1 wk prior to stopping steroids to prevent rebound
 - Follow acute phase reactants (erythrocyte sedimentation rate, C-reactive protein)
- Other treatment depends on severity of involvement and symptoms
 - Moderate-to-severe carditis: consider salt and fluid restriction, diuretics, afterload reduction as temporizing measures
 - Intractable heart failure: surgery

TABLE 60.7 Treatment of Chronic Rheumatic Heart Disease

- General medical management
 - Serial evaluation
 - Recognition of progression, symptoms
 - Echocardiography: valvular function, chamber sizes, ventricular function, pulmonary pressures
 - Education: early recognition of symptoms, prevent complications
 - Secondary prophylaxis
 - Infective endocarditis prophylaxis when indicated (see text)
 - Activity restrictions based on severity of valvular disease
- Mitral regurgitation (MR) (severe)
 - Specific medical management: none; no defined role for afterload reduction
 - Indications for surgery: symptoms, LV dysfunction, marked ventricular enlargement, new-onset atrial fibrillation, pulmonary hypertension (possible intervention for severe MR in asymptomatic patients with preserved LV function if valve repair likely in a center with expertise)
- Aortic regurgitation (severe)
 - Specific medical management: vasodilator therapy for patients with symptoms or LV dysfunction who are poor surgical candidates (cardiac or noncardiac reasons); vasodilator therapy may also be used for short term to improve hemodynamics prior to aortic valve surgery
 - Indications for surgery: symptoms, ventricular dysfunction, marked LV enlargement, and for patients undergoing other cardiac surgery (coronary, other valves, etc.)
- Mitral stenosis
 - Specific medical management: anticoagulation is recommended for (1) history of thromboembolic event, (2) atrial fibrillation, and (3) left atrial thrombus; possible role for rate control in selected cases
 - Indications for mechanical intervention (catheter-based or surgical): symptoms, pulmonary hypertension
 - Percutaneous balloon valvotomy: best results for those with echocardiographic evidence of noncalcified and pliable leaflets, without severe thickening or subvalvular pathology
 - Surgery (repair if possible; valve replacement) in patients not candidates for percutaneous intervention (expertise not available, left atrial thrombus, significant associated mitral regurgitation, unfavorable mitral valve morphology)
- Aortic stenosis (severe)
 - Specific medical management: none
 - Percutaneous treatment (catheter-based balloon valvotomy or transapical or transcatheter aortic valve implantation) is reserved for those who are poor surgical candidates
 - Indications for surgery: symptoms, LV dysfunction, and patients undergoing other cardiac surgery

Traditionally, many patients with RF have been hospitalized for evaluation, diagnosis, and initiation of appropriate treatment. In our experience, the majority of patients can be both evaluated and managed as outpatients.

Medical Management of Acute RF

In addition to a careful history and physical examination, patients with suspected RF should have a throat culture performed, lab tests including ASO and/or anti-DNase b titers, a white blood cell count, and acute phase reactants (erythrocyte sedimentation rate and C-reactive protein), an ECG, and an echocardiogram (if possible) (Table 60.3). Admission to the hospital should be considered, but some patients can be managed as outpatients with close follow-up.

Management of acute rheumatic carditis should include antibiotic treatment to eradicate pharyngeal streptococci, bed rest (262,263), and anti-inflammatory treatment (Table 60.5) (66,173,264–269). Although there is no evidence that it alters the course of RF, antibiotic therapy is recommended even if the throat culture is negative. In the 1940s, RF patients who were allowed to ambulate had a longer duration and greater severity of carditis (larger heart size on CXR) and more frequent reactivations than those placed at bed rest. Some restriction of activity during the acute phase is warranted, but the prolonged strict bed rest practiced in the 1940s and 1950s is probably unnecessary (269). Some experts recommend bed/chair rest for 4 to 6 weeks for patients with carditis, depending on the severity. Although of unproven benefit, many recommend anti-inflammatory treatment with either aspirin or steroids for patients with rheumatic carditis since a subset of patients with significant acute rheumatic mitral and/or aortic regurgitation improves as the acute inflammation subsides (270). There is no clear-cut evidence that steroids are superior to aspirin in affecting long-term outcome (271). However, compared to aspirin, steroids do result in a more prompt resolution of inflammation (272,273), fewer new murmurs (274), and more rapid disappearance of existing murmurs (275). Many experts recommend aspirin at a dose of 80 to 100 mg/kg/d (doses as high as 4 to 6 g/d for adults) for mild-to-moderate carditis. Salicylate levels should be checked, aiming for serum concentrations of 20 to 30 mg/dL. For patients with moderate-to-severe carditis and heart failure, many recommend steroids (prednisone 2 mg/kg/d or equivalent) for approximately 2 weeks, followed by tapering doses (reduce by 20% to 25% each week). Salicylates are started about a week prior to discontinuing steroids to prevent rebound. The optimal duration of anti-inflammatory treatment with salicylates and/or steroids is unknown; some recommend treatment for 4 to 6 weeks, while others recommend treatment until there is laboratory evidence of resolution of the acute inflammatory process (i.e., normalization of erythrocyte sedimentation rate and/or C-reactive protein). Although laboratory and clinical rebound may be seen following discontinuation of anti-inflammatory therapy, this usually resolves spontaneously without the need for reinstitution of therapy (7,156,266). While some patients with heart failure improve, it should be emphasized that for patients with severe valvular regurgitation and heart failure unresponsive to medical therapy, surgical restoration of valvular competence (repair or replacement) may be life saving (26). Neither intravenous gamma globulin (276) nor pentoxifylline (277) has been found to be of benefit.

As previously stated, the arthritis of RF is typically very responsive to aspirin within 48 to 72 hours. Nonsteroidal anti-inflammatory agents have been reported as an effective alternative to aspirin for patients with polyarthritis, but have not been evaluated for the treatment of carditis (278,279).

The duration of anti-inflammatory treatment for rheumatic arthritis can usually be guided by symptoms and response to therapy.

Most patients with chorea can be managed without pharmacologic treatment. In cases with severe symptoms, reported treatments include phenobarbital, haloperidol, valproic acid, corticosteroids, plasma exchange, and intravenous immune globulin (280–284).

Medical Management of Acute Rheumatic Carditis and Heart Failure

As stated above, many clinicians experienced in the management of RF and acute carditis recommend steroids for patients with acute heart failure (see section above). Although some of the older literature suggests a role for digoxin (50,266,285), this may have been due to the belief that myocardial dysfunction played an important role in rheumatic carditis. It should be emphasized that the primary hemodynamic abnormality is valvular incompetence rather than myocardial dysfunction. Diuretics and afterload reduction may be valuable as temporizing measures in patients with significant regurgitation and symptoms. However, in cases with intractable heart failure, surgical restoration of valvular competency (repair or replacement) may be life saving (191,286). In particular, patients with a flail mitral valve after chordal rupture do not respond to medical management and require surgery (189,223) (Table 60.6).

Medical Management of Chronic RHD

Guidelines for the management of chronic RHD are given in Table 60.7. In the absence of data on the natural history and impact of treatment on chronic valvular disease in children, many practitioners extrapolate from the adult literature and guidelines (194). Asymptomatic patients with rheumatic valvular disease can often be followed conservatively as most remain stable for years. In the absence of symptoms, medical management should include serial evaluation to detect interval change and/or the onset of symptoms, prevent complications (i.e., recurrent RF, endocarditis, or embolic events), and detect changes in valvular function, chamber sizes, and ventricular function. Anticoagulation with warfarin is recommended for patients with mitral stenosis who have a history of a prior embolic event and for those who have atrial fibrillation (194).

The role of afterload reduction in the management of asymptomatic patients with chronic severe mitral regurgitation and preserved left ventricular function remains unclear. Although some studies have demonstrated improvement in hemodynamic variables (287–289), other studies have suggested that vasodilators might result in hemodynamic worsening (290,291). At present, there are no long-term studies showing afterload reduction in this setting to delay the onset of symptoms or ventricular dysfunction or improve outcome. Thus, use of afterload reduction in the management of asymptomatic patients with chronic mitral regurgitation who have preserved left ventricular function is not recommended (194,292,293). Once symptoms develop, medical management of mitral or aortic regurgitation has little role except as a temporizing measure, and surgical intervention is indicated (194).

There is conflicting evidence regarding the role of afterload reduction for the management of asymptomatic adults with chronic, severe aortic regurgitation and preserved left ventricular function. One study comparing long-acting nifedipine with digoxin in a prospective randomized trial found that fewer patients in the nifedipine group underwent aortic valve replacement (symptoms or LV dysfunction) (294).

A subsequent study comparing placebo, long-acting nifedipine, and enalapril found no difference in the treatment groups with respect to development of symptoms or LV dysfunction (295). Accordingly, the current American College of Cardiology/American Heart Association Guidelines for the Management of Patients With Valvular Heart Disease do not recommend vasodilator therapy for long-term management of asymptomatic patients with severe aortic regurgitation who have normal ventricular systolic function (194,294–296).

Unfortunately, there are even less data to guide management of patients with combined mitral and aortic regurgitation. Although symptoms are an indication for surgical intervention, there is evidence suggesting that by the time such patients are symptomatic, the likelihood that left and right ventricular functions are compromised is greater than in similar patients with isolated mitral or aortic regurgitation. Since right ventricular function is a valuable predictor of postoperative mortality in patients with combined left-sided valvular regurgitation, detection of decreased right (or left) ventricular function should prompt referral for surgical intervention (297).

Recently, investigators have reported possible benefit from the use of statins on progression of chronic RHD. Retrospective studies have suggested that statins may slow the progression of both rheumatic mitral and aortic stenosis. The mechanism remains unclear; the anti-inflammatory properties of statins may play a role. Results from prospective trials in adults with valvar aortic stenosis have yielded conflicting results. Thus, although the possibility of medical therapy that can change the natural history of RHD (separate from preventing RF recurrences) is intriguing with important potential, the role of statins in the management of chronic RHD remains undefined (298–302).

Heart Failure in Chronic RHD

Guidelines for the management of patients with RHD and heart failure are given in Table 60.7. There is no role for long-term medical management of patients with *symptomatic* chronic mitral and/or aortic regurgitation. Unless surgery is contraindicated for other reasons, such patients should be referred for surgery (194,292).

Patients with rheumatic *mitral stenosis* and mild symptoms such as dyspnea on exertion related to higher heart rates may benefit from negative chronotropic agents, such as beta-blockers or calcium channel blockers. Judicious use of diuretics and/or sodium restriction may be valuable in cases with pulmonary venous congestion (194). With significant stenosis and symptoms, both percutaneous balloon valvuloplasty (303,304) and surgical intervention have been effective (305). An echocardiographically determined mitral valve morphology score combining assessment of leaflet mobility, subvalvular thickening, leaflet thickening, and leaflet calcification has been found to be a predictor of outcome after balloon valvuloplasty for mitral stenosis (241,243,306). Symptomatic patients who are not candidates for percutaneous balloon valvuloplasty should be referred for surgery.

There is no effective medical therapy for symptomatic rheumatic *aortic valve stenosis*. Unlike congenital aortic valve stenosis in children, balloon valvuloplasty is not effective and has a limited role in the treatment of symptomatic calcific aortic valve stenosis (307,308); it should be reserved for patients who are unacceptable surgical candidates (194).

Similarly, medical management of symptomatic rheumatic *tricuspid valve disease* is unlikely to be successful. Diuretics may be useful as a temporizing measure in symptomatic patients, but optimal treatment is surgical commissurotomy, usually at the time of concomitant mitral valve surgery (309).

SURGICAL AND CATHETER-BASED TREATMENT

(See Tables 60.6 and 60.7). Acute Carditis

Some patients with significant acute mitral or aortic regurgitation improve with time as the inflammation subsides, while others have intractable or progressive heart failure that is unresponsive to medical therapy. *Surgical intervention with valvuloplasty or valve replacement during the acute illness can be life-saving because valvular regurgitation rather than myocardial dysfunction is the underlying problem*, and restoration of valvular competence results in significant clinical improvement (197). Despite earlier reports of higher reoperation rates and surgical mortality for repair performed during the acute period (310,311), more recent investigators have shown no relationship to rheumatic activity, with mortality rates <5% (197,264,311,312). Because the dominant abnormalities underlying acute rheumatic mitral regurgitation are annular dilation and chordal elongation resulting in poor leaflet coaptation, surgical annuloplasty and/or chordal shortening have been performed with good results (186,197).

Chronic RHD

Rheumatic valvular disease is often progressive, resulting in a chronic hemodynamic burden that may require surgical intervention (211). Determining the optimal time for surgical intervention in children with chronic RHD is often difficult. The presence of significant symptoms is a logical and accepted indication, but the optimal timing of intervention for asymptomatic children is unclear. With little data to guide the timing of intervention for rheumatic valvular disease in children, many extrapolate from the guidelines for intervention in adults with valvular heart disease (194,243).

The primary indications for surgical intervention for adults with chronic severe *mitral regurgitation* are symptoms and/or left ventricular dysfunction. Additional indications include marked ventricular enlargement, atrial fibrillation, and pulmonary hypertension (194,237). Recently, some have advocated surgery in asymptomatic patients with severe mitral regurgitation and preserved ventricular function if valve repair rather than replacement is likely and can be performed with low morbidity and mortality (313). An effective regurgitant orifice area >40 mm² (314) or elevation of B-type natriuretic peptide (315) should also warrant careful evaluation and consideration, although when to refer such patients for surgical intervention remains controversial (316). The rheumatic mitral valve can be repaired using techniques including commissuroplasty, debridement, or thinning of the anterior leaflet, often in conjunction with a mitral annuloplasty (317–321). In some cases, the mitral valve cannot be repaired and must be replaced with a prosthetic valve (143,322).

Indications for surgical intervention for chronic *aortic regurgitation* are similar to those for mitral regurgitation and include symptoms, ventricular dysfunction, and marked ventricular enlargement (194). When surgery is indicated, the valve may be repaired or replaced. Historically, most aortic valves warranting intervention have been replaced, but there is increasing experience with valve repair techniques including commissuroplasty, leaflet shortening, and aortic cusp extension (286,310,323,324). Similar to the case with mitral valves, some valves are not amenable to repair and must be replaced. Although pulmonary autograft replacement of the aortic valve (Ross procedure) has been performed on some patients with rheumatic aortic valve disease, the autograft has been shown to be susceptible to rheumatic involvement with an increased risk of valve failure and reoperation (258,325,326).

Indications for intervention for chronic rheumatic *mitral stenosis* include symptoms and/or pulmonary hypertension (194,327). Although open mitral commissurotomy and mitral valve replacement were the surgical procedures of choice in the 1960s and 1970s, percutaneous balloon valvotomy has evolved as an accepted alternative to surgery in selected patients. Immediate results are similar to those of surgical commissurotomy, with success rates of >80% to 95%, doubling of valve area, and a 50% to 60% reduction in transmitral gradient. In addition to being operator dependent, results from percutaneous valvotomy are strongly influenced by patient factors and the morphology of the mitral valve. Patients whose mitral valves are noncalcified with mobile leaflets, without severe leaflet thickening or subvalvular pathology are the best candidates for percutaneous valvotomy, with the highest likelihood of immediate and sustained improvement with a low complication rate (240,241,327). Relative contraindications to percutaneous intervention for mitral stenosis include the presence of a left atrial thrombus and significant mitral regurgitation. When surgery is indicated for rheumatic mitral stenosis, open commissurotomy rather than valve replacement should be performed when possible. Results are similar to those reported for percutaneous valvotomy. When the valve is not amenable to repair, mitral valve replacement is performed with an operative risk of less than 5% in the absence of pulmonary hypertension or other comorbidities (194,328). For mitral stenosis patients who are judged to be good candidates for percutaneous balloon valvotomy, many cardiologists will schedule intervention somewhat earlier in the course than for surgical intervention. Conversely, if mitral valve replacement appears more likely than repair, stricter indications are used, and patients are often sent to surgery later in the course of the mitral valve disease (194,240).

As opposed to patients with congenital aortic valve stenosis in whom intervention is often guided by pressure gradient, indications for intervention for rheumatic *aortic stenosis* are symptoms (angina, syncope, and heart failure), left ventricular dysfunction, or an abnormal response to exercise (symptoms, hypotension, ventricular arrhythmias, impaired exercise tolerance, and new ST segment depression) (194). Also different from congenital aortic valve stenosis is the limited role for percutaneous balloon valvotomy in treating rheumatic aortic valve stenosis; studies have shown a less than optimal improvement in valve area associated with a significant complication rate in this setting (194). Thus, patients meeting indications for intervention should undergo aortic valve

replacement (see aortic regurgitation section for discussion of Ross procedure in this setting).

The surgical approach to rheumatic *tricuspid valve disease* is based on the underlying abnormality. A tricuspid annuloplasty may be performed for tricuspid regurgitation due to annular dilation. Tricuspid commissurotomy is the preferred approach to rheumatic tricuspid stenosis (247,249,252,309).

PREVENTION AND PROPHYLAXIS

Efforts to decrease the incidence of RF and the prevalence and severity of RHD and to prevent complications are focused on a combination of primary prophylaxis, secondary prophylaxis, improving living conditions and developing a vaccine (primordial prophylaxis), and medical management including endocarditis prophylaxis (Fig. 60.8).

Primary Prophylaxis

It is well established that appropriate treatment of streptococcal pharyngitis markedly decreases the risk of developing RF if started within 9 days after the onset of symptoms (11,23,165,329,330). Unfortunately, for as many as one-third to two-thirds of patients, the GAS pharyngitis is subclinical (60), precluding effective primary prevention. Even with a negative throat culture, all patients diagnosed with acute RF should be treated to eradicate GAS from the pharynx and prevent repetitive antigenic stimulation (165). A single intramuscular injection of benzathine penicillin is the most effective treatment, but oral penicillin is an alternative, requiring compliance with the full 10-day treatment course (Table 60.8). Penicillin-allergic patients should receive a narrow-spectrum cephalosporin, clindamycin, clarithromycin, or azithromycin, although some patients allergic to penicillin may also be allergic to cephalosporins (331). Penicillin-resistant strains of GAS have not been reported (266), and follow-up cultures are not necessary. Although some have suggested other antibiotics for the treatment of GAS pharyngitis (126), penicillin remains the treatment of choice for GAS pharyngitis. The American Heart Association, Infectious Disease Society of American, the American College of Physicians-American Society of Internal Medicine, American Academy of Family Physicians, and the U.S. Center for Disease Control

Figure 60.8. Prevention (and management) of acute RF and RHD. RF, rheumatic fever; RHD, rheumatic heart disease.

TABLE 60.8 Treatment of Streptococcal Pharyngitis (Primary Prophylaxis)

Benzathine penicillin G
600,000 U intramuscularly once for patients ≤ 27 kg
1.2 million U intramuscularly once for patients > 27 kg
or
Phenoxymethylpenicillin (penicillin V)
250 mg orally BID or TID for 10 d for patients ≤ 27 kg
500 mg orally BID or TID for 10 d for patients > 27 kg
or
Amoxicillin 50 mg/kg orally once daily for 10 d (max 1 g/dose)
Penicillin-allergic patients
Cephalosporin (narrow-spectrum): dosage regimen depends on agent, ^a oral for 10 d
Clindamycin: 20 mg/kg/d orally divided in three doses for 10 d (max 1.8 g/d)
Azithromycin: 12 mg/kg orally once daily for 10 d (max 500 mg)
Clarithromycin: 15 mg/kg/d orally divided in two doses for 10 d (max 250 mg per dose)

^aUp to 10% of penicillin-allergic individuals are also allergic to cephalosporins. From Gerber MA, Baltimore RS, Eaton CB, et al. Prevention of rheumatic fever and diagnosis and treatment of acute streptococcal pharyngitis: a scientific statement from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee of the Council on Cardiovascular Disease in the Young, the Interdisciplinary Council on Functional Genomics and Translational Biology, and the Interdisciplinary Council on Quality of Care and Outcomes Research; endorsed by the American Academy of Pediatrics. *Circulation* 2009;119:1541–1551.

all recommend that GAS pharyngitis be treated for 10 days with oral penicillin or with long-acting benzathine penicillin (55,165,332). Although primary prophylaxis is both recommended and effective for individual patients, it remains unclear and controversial whether it is effective in decreasing the overall incidence of RF (109,333–336). Administration of antibiotics during an episode of RF does not alter the course or severity of cardiac involvement (115). No studies have shown tonsillectomy to be effective in reducing the incidence of RF.

Secondary Prophylaxis

In the absence of specific and effective treatment for RF, preventing RF recurrences is the most effective means of decreasing the likelihood and severity of long-term chronic RHD (7). All patients who have had RF, especially those with cardiac involvement, are at risk for recurrences. Some studies report this risk to be as high as 40% to 60% for patients with cardiac involvement (47,264,337). The risk of recurrence is greatest in the first few years following an episode of RF, and then decreases with time. The pattern of clinical involvement with such recurrences is often mimetic, following the pattern of the initial episode. Thus, patients who have carditis with their first episode of RF are likely to have cardiac involvement with recurrences. The recurrences often result in more severe rheumatic valvular dysfunction and a greater likelihood of significant chronic RHD (44,338). Unfortunately, the mimetic clinical pattern with recurrences is not absolute, and a minority (6% to 14%) of patients develops clinical carditis and subsequent RHD only after a recurrence (114,338,339).

TABLE 60.9 Secondary Prophylaxis After RF

Benzathine penicillin G
600,000 U intramuscularly every 3–4 wk for patients ≤ 27 kg (60 lb)
1.2 million U intramuscularly every 3–4 wk for patients > 27 kg (60 lb)
or
Phenoxymethylpenicillin (penicillin V)
250 mg orally twice daily
or
Sulfadiazine
0.5 g orally once daily for patients ≤ 27 kg
1 g orally once daily for patients > 27 kg
Penicillin- and sulfa-allergic patients
Macrolide or azalide (dose depends on agent and patient size)

Category	Duration
RF with carditis and residual RHD (clinical or echocardiographic)	10 y since last episode or until age 40 y ^a ; possibly lifelong
RF with carditis, but no residual RHD	10 y or until age 21 y ^a
RF without carditis	5 y or until age 21 y ^a

^aWhichever is longer.

From Gerber MA, Baltimore RS, Eaton CB, et al. Prevention of rheumatic fever and diagnosis and treatment of acute streptococcal pharyngitis: a scientific statement from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee of the Council on Cardiovascular Disease in the Young, the Interdisciplinary Council on Functional Genomics and Translational Biology, and the Interdisciplinary Council on Quality of Care and Outcomes Research; endorsed by the American Academy of Pediatrics. *Circulation* 2009;119:1541–1551.

Thus, all patients who have had RF should receive secondary prophylaxis to prevent recurrences (Table 60.9). Intramuscular administration of benzathine penicillin (1.2 million units) is the most effective secondary prophylaxis regimen. In many areas, this injection is administered every 4 weeks. However, there is pharmacokinetic evidence that penicillin levels fall between 21 and 28 days after administration in a significant proportion of patients (340). Thus, in areas where RF is endemic and/or in cases with a documented RF recurrence on every 4-week prophylaxis, every 3-week administration of intramuscular penicillin may be preferable (Indian Academy of Pediatrics recommends every 2 weeks for some patients) (341,342). Oral penicillin is a reasonable alternative, especially in parts of the world where RF is less common and in low-risk cases (165,331). Sulfadiazine is recommended for patients allergic to penicillin. Recent reports emphasize the importance of noncompliance in the evolution of heart disease and precipitation of congestive heart failure in an at-risk population (343).

The recommended duration of secondary prophylaxis is influenced by the presence of acute and chronic cardiac involvement and by the time since the last episode of RF (Table 60.9) (165). Since patients who have had carditis are at higher risk for cardiac involvement with recurrences, the recommended duration of secondary prophylaxis is longer for this group of patients. In selected low-risk patients (e.g., no carditis or RHD) more than 5 years out from the RF illness,

discontinuation of prophylaxis earlier than suggested in the guidelines of Table 60.9 may be justified (344). Some recommend that patients with persistent RHD receive secondary prophylaxis indefinitely (165,267), while others have suggested that prophylaxis is unnecessary beyond age mid-20s (286). Patients should continue to receive secondary prophylaxis even after valve replacement since recurrence may result in damage to other cardiac valves (345). Allergic (3%) and anaphylactic (0.2%) reactions to monthly benzathine penicillin infections are uncommon and are unrelated to the duration of prophylaxis (7).

Unfortunately, many patients with RHD do not receive secondary prophylaxis, for at least two reasons. First, in order for secondary prophylaxis to be effective in reducing the prevalence and evolution of chronic RHD, patients who would benefit from such a prophylaxis program must be identified. Many patients with RHD do not recall having had prior RF and are unaware of their heart disease until they either develop symptoms or have their valvular abnormality detected incidentally. The World Health Organization recommends school-based screening to identify such patients, but the optimal method for screening remains to be established. Two reports of school-based screening using echocardiography performed in Mozambique and Cambodia found the prevalence of RHD detected using echocardiography to be 10 to 13 times greater than using clinical auscultation alone (346). Thus, 90% of RHD cases were only detected by echocardiography. A similar study performed in Tonga yielded a similar prevalence of RHD using echocardiography (347). There continues to be debate regarding the diagnosis of subclinical RHD. It is well known that many patients who present with RHD cannot recall having prior RF and that a significant proportion of patients with “pure” chorea (no clinical carditis) go on to develop chronic RHD (suggesting very mild or subclinical cardiac involvement). On the other hand, small amounts of valvular regurgitation can be seen in normals (“physiologic”) so that differentiation between mild pathologic and physiologic regurgitation can be difficult, leading to the potential for overdiagnosis. To address this difficulty, criteria have been evaluated and proposed that help distinguish physiologic from pathologic Doppler regurgitation (7,219,222,225,226). In addition, some have proposed that both 2-D morphologic changes and Doppler evidence of valvular regurgitation be required for the diagnosis of subclinical RHD (25). However, this requirement risks underdiagnosis as many patients with mild RHD show clearly pathologic valvular regurgitation with minimal morphologic changes.

Second, once patients who would benefit from secondary prophylaxis have been identified, compliance must be optimized. Both the World Health Organization and World Health Federation recommend register-based control programs to promote education, training, and early recognition of RF and RHD and to optimize and coordinate the delivery of secondary prophylaxis in populations with a high prevalence of RHD. Although establishing and sustaining such programs is challenging, especially in developing countries, the potential benefits of such programs are significant and form the basis of the joint global project on RF/RHD prevention and promotion (6,7,109).

Primordial Prevention

The fact that as many as one-third to two-thirds of cases of RF are preceded by a minimally symptomatic or asymptomatic GAS pharyngitis makes effective *primary prophylaxis* impossible in many cases. Poor access to health care in developing countries where the incidence of RF is high further decreases the likelihood of effective primary prophylaxis. If the initial episode of RF is not recognized, *secondary prophylaxis* (to

prevent recurrences) cannot be implemented. Even when the initial episode is diagnosed, poor compliance with long-term secondary prophylaxis may further limit effective prevention of RF recurrences that may lead to progressive RHD (6). While secondary prophylaxis is the most cost-effective approach to preventing RHD once a patient is known to have had RF/RHD, the most effective way to decrease the burden of RF and RHD in developing countries may be by reducing exposure to GAS, termed by some as “primordial prophylaxis.” Such primordial prevention can occur in at least two ways. Since improvement in socioeconomic conditions in industrialized countries has led to a significant decrease in the incidence of RF and the prevalence of RHD, it is not unreasonable to think that similar improvements in developing countries may result in similar benefit. There is also ongoing work to develop an effective GAS vaccine. Challenges in the development of such a vaccine include the fact that it must be multivalent (accounting for the numerous M types that may lead to RF), safe (cross-reactive antibody has the potential to produce significant unwanted side effects), and would be preferably mucosal (administered intranasal or orally rather than by injection) (7,109,348,349).

Endocarditis Prophylaxis

Endocarditis continues to be an important complication of RHD (8,350). The American Heart Association Guidelines for endocarditis prophylaxis were revised in 2007 such that prophylaxis is now recommended for patients undergoing dental procedures with cardiac conditions associated with the highest risk of adverse outcome from endocarditis. This includes patients with prosthetic cardiac valves or prosthetic material used for cardiac valve repair and those who have had previous endocarditis. Prophylaxis is no longer recommended for patients with other conditions (including many patients with RHD). Prophylaxis is recommended for “dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa,” but is no longer recommended for gastrointestinal or genitourinary procedures (351). The reader is referred to the Guideline statement for details regarding patient selection and antibiotic regimen. Since patients receiving chronic penicillin prophylaxis are likely to be colonized with amoxicillin-resistant organisms, clindamycin, clarithromycin, or azithromycin are recommended for indicated procedures (351,352).

SUMMARY

- RF and RHD continue to be major problems in developing countries, resulting in significant morbidity and mortality.
- Factors related to the streptococcal organism, the environment, and host susceptibility influence the likelihood of an individual developing RF.
- The pathogenesis of RF is likely related to an abnormal immune response to a preceding GAS infection; both humoral and cell-mediated immune responses contribute to the clinical manifestations, including acute carditis and chronic RHD.
- The most common clinical manifestations of RF are arthritis, carditis, and chorea; carditis and subsequent RHD are responsible for long-term morbidity and mortality.
- Diagnostic criteria should serve as guidelines to assist in the diagnosis of both initial and recurrent attacks of RF. In areas where RF and RHD continue to be common, modification of the diagnostic criteria (e.g., polyarthralgia, monoarthritis, and silent carditis as major criteria) may improve sensitivity and decrease underdiagnosis.

- Valvular dysfunction (rather than myocarditis or pericarditis) is the important abnormality in both acute rheumatic carditis and chronic RHD.
- Echocardiography should be performed (if available) on all patients with RF. It is useful in confirming and quantifying valvular regurgitation, in differentiating acute RHD from innocent murmurs or congenital heart disease, in the serial evaluation of patients with known RHD, and in identifying subclinical rheumatic cardiac involvement. The World Health Organization recommends that silent but significant mitral and/or aortic regurgitation be considered *probable* RHD, and that such patients be given secondary prophylaxis and followed long-term for evolution of heart disease. Guidelines from Australia and New Zealand recommend that subclinical rheumatic carditis be accepted as a major criterion in diagnosing RF.
- The most important factors influencing the likelihood and severity of chronic RHD are the severity of the initial carditis, and RF recurrences.
- Primary prophylaxis (treatment of GAS pharyngitis) is effective in preventing RF, but many cases go untreated (very mild symptoms or subclinical pharyngitis).
- Preventing recurrences of RF (secondary prophylaxis) is the most effective means of decreasing the likelihood and severity of long-term RHD.
- The most effective way to decrease the burden of RF and RHD in developing countries may be via improvement in living conditions (crowding, hygiene, access to care) and development of an effective vaccine against GAS ("primordial prophylaxis"); efforts are ongoing in these areas.
- Mechanical intervention techniques for RHD continue to improve. Percutaneous balloon valvotomy is effective in many patients with rheumatic mitral stenosis, and both mitral valve and aortic valve repair (as opposed to replacement) are being performed more commonly, with better outcomes.

Inflammatory Noninfectious Cardiovascular Diseases

Charles H. Spencer ■ Anjali Patwardhan ■ Sharon L. Roble

The chronic, multisystem rheumatic diseases of childhood affect many body organs, including the cardiovascular system. This chapter discusses the juvenile idiopathic arthritis (JIA), systemic lupus erythematosus (SLE), vasculitis syndromes, and other rheumatic diseases briefly and then focuses on their cardiac complications. The differential diagnosis of each cardiac complication is discussed as well.

JUVENILE IDIOPATHIC ARTHRITIS

JIA is an uncommon chronic arthritis disease in children. In the United States, close to 300,000 children have chronic arthritis diseases (1). The incidence of new cases ranges from 1 to 20 per 100,000 per year (2,3). The burden of JIA remains considerable despite the newest therapies, including biologics (3). Improvement in the outcome of JIA will require earlier diagnosis and aggressive early therapy as well as improvement in the therapy, understanding of the environmental triggers, and genetic predisposition.

Diagnosis

The diagnosis of JIA requires symptoms and the presence of arthritis on physical exam for at least 6 weeks. Other potential causes of arthritis must be considered and excluded. JIA has different subtypes that may evolve over the initial 6 months. Subtypes are differentiated by clinical features and the number of joints that become involved. Subtypes include systemic-onset JIA, oligoarticular JIA, rheumatoid factor (RF) negative polyarticular JIA, RF positive polyarticular JIA, psoriatic JIA, and enthesitis-related JIA (ERJIA) (Table 61.1).

Systemic-onset JIA is a systemic illness characterized by a triad of daily spiking fevers, an evanescent macular rash, and arthritis involving at least one joint. Some patients will have hepatosplenomegaly and lymphadenopathy. Oligoarticular JIA typically presents with arthritis in four or fewer joints affected and lack of systemic symptoms (4). RF negative polyarticular JIA typically affects five joints or more with a less symmetrical small and large joint arthritis than seen in the RF positive polyarticular JIA. RF positive polyarticular JIA closely resembles adult rheumatoid arthritis (RA). Psoriatic arthritis has its own personality with a very asymmetrical arthritis and a family history of psoriasis; the psoriatic rash may not be present at the onset of the arthritis. Enthesitis-related arthritis affects boys more often with the characteristic enthesitis, which involves inflammation of tendons and ligaments at points of insertion, as well as lower extremity arthritis. Each one of these JIA subtypes has its own very distinct clinical pattern (5).

Clinical Patterns for Diagnosis

Systemic-Onset Juvenile Idiopathic Arthritis

Systemic-onset JIA is an impressive systemic inflammatory disease that may have more in common with autoinflammatory diseases than the other subtypes of JIA (4). It may involve multiple target organs including the joints, skin, lymph nodes, liver, spleen, heart, and lungs. There is no distinct peak age of onset of systemic-onset JIA. The systemic presentation is often impressive with daily high spiking fevers associated with a pale, pink, evanescent small macular rash (Fig. 61.1), more on the trunk than the extremities. The rash is especially evident when the fever is at its peak. The child often suffers from terrible muscle and joint pains during the fever spike and is quite irritable. Arthritis may begin early in the course of the disease or may present later, sometimes up to several months after the onset of the disease. The arthritis usually follows a polyarticular pattern.

Laboratory testing reveals systemic inflammation with frequent leucocytosis, thrombocytosis, markedly elevated sedimentation rate, and a normocytic, normochromic anemia. The serum ferritin is often significantly elevated as well. Serologies including the antinuclear antibody (ANA) titer and the RF are negative. Though this presentation is classic for systemic-onset JIA, it is prudent to consider infections and malignancy in the differential diagnosis as there is not one diagnostic symptom, sign, or laboratory test for this subtype of JIA. The diagnosis is made by recognition of the clinical pattern of fever, rash, and arthritis with compatible laboratory testing and a negative infectious and malignancy evaluation, often including a bone marrow biopsy. The systemic features of systemic-onset JIA often remit with time and the course of these children follows a polyarthritis pattern.

Oligoarticular JIA

This subtype of JIA is seen most often in young girls with a peak of onset between 1 and 2 years of age. The children often develop one or several swollen large joints, usually one knee or both knees followed by ankles (Fig. 61.2). The arthritis typically begins in one joint and over the first 6 months, the child has only four or fewer joints involved. Despite the limited number of joints affected, the child can be disabled, for example, with difficulty walking, especially in the morning. The child may have major joint difficulties with pain, stiffness, and flexion contractures, but does not usually have systemic features such as fevers, rash, or hepatosplenomegaly. Uveitis is a major complication of this type of arthritis (Fig. 61.3). It is occasionally present at the time of diagnosis of the arthritis but more often develops over the next few years in a minority

TABLE 61.1 Multimodality Imaging for Diagnosis of Cardiac Sarcoidosis

Diagnostic Test	Feature	Sensitivity	Specificity
Electrocardiogram	Conduction disturbances, arrhythmias	Low	Low
Echocardiography	Abnormal wall motion, regional wall thinning/thickening, depressed ejection fraction, pericardial effusion	Low to moderate	Low
201 Thallium scintigraphy	Segmental perfusion defect	Moderate	Moderate
67 Gallium scintigraphy	Increased myocardial uptake	Low	High
18F FDG-PET	Increased myocardial uptake	High	Moderate to high
CMR	High intensity lesions, thinning of ventricular wall	Moderate to high	High

FDG-PET, fluorodeoxyglucose positron emission tomography; CMR, cardiac magnetic resonance

of these oligoarticular children. The diagnosis of this subtype is made by the presence of typical joint involvement for at least 6 weeks. Laboratory tests are nonspecific. Synovial fluid analysis may reveal an inflammatory range of the white blood cell (WBC) count, a shift to the left in the WBC differential and normal synovial fluid glucose, protein, and cultures. The complete blood count (CBC) is usually normal and sedimentation rate may be elevated or normal. The ANA is often mildly elevated and RF negative.

A swollen joint of brief duration must be evaluated for a septic joint, osteomyelitis, trauma, hemarthrosis, and other acute processes. Most often these problems have been excluded by the time the diagnosis of oligoarticular JIA is considered. A minority of these oligoarticular JIA children will develop polyarthritis over time and are classified as extended oligoarticular JIA.

Rheumatoid Factor Negative Polyarticular JIA

This type of JIA occurs more in girls and begins both early in childhood and in older children and adolescents. These children develop arthritis in more than four joints in the first 6 months of the disease process. Small and large joints are affected as well as the cervical spine and the temporomandibular joint (TMJ) (Fig. 61.4). Disability can be profound.

Figure 61.1. The macular evanescent rash of systemic JIA on the thigh of a 12-year-old boy.

The number of joints affected may increase over time and the hips may eventually become involved. Systemic features such as fever, rash, serositis, and organomegaly are not typically present; however, uveitis may occur along with growth failure, fatigue, and malaise. Psoriatic disease as well as ankylosing spondylitis, reactive arthritis, inflammatory bowel disease, and other spondyloarthropathies must be excluded. Scleroderma and dermatomyositis may cause polyarthritis but have their own distinguishing skin and muscle features for diagnosis. Infections such as multiple-joint or bone septic processes, parvovirus disease, Lyme disease, and disseminated *Neisseria gonorrhoeae* may sometimes mimic polyarthritis due to JIA. Malignancies such as leukemia, lymphoma, and neuroblastoma may also mimic JIA.

Laboratory tests show mild, nonspecific abnormalities. Mild anemia of chronic disease may be present and occasionally the platelet count is elevated as an acute phase reactant. The sedimentation rate is often elevated. The ANA titer may be mildly elevated.

Rheumatoid Factor Positive Polyarticular JIA

Older children and adolescents may develop an arthritis disease involving joints or more with a positive RF (5). The RF should

Figure 61.2. A swollen, limited wrist of a 10-year-old girl with polyarticular RF negative JIA.

Figure 61.3. The swollen knees and ankles of a 13-year-old girl with severe RF negative JIA.

be positive on two or more occasions in tests done at least 3 months apart. This subtype is an overwhelmingly female disease and is very similar to adult RA. Small and large joints may be involved and, as in RF-polyarticular JIA, the cervical spine and TMJ are frequently affected. Rheumatoid nodules typical of adult RA are not uncommon, especially on the hands, feet, and elbows (Fig. 61.5). Uveitis may also occur. Systemic features such as fever and rash are rare although poor weight gain, fatigue, and malaise are common. The differential diagnosis is limited due to the utility of the positive RF, which, in lieu of any typical signs of other diseases, facilitates the diagnosis of polyarticular JIA. Although the specificity and sensitivity of the anti-cyclic citrullinated peptide antibody (anti-CCP) is not yet clear in children and adolescents, it holds promise for diagnosing RF positive JIA early in the disease course (6).

Figure 61.4. The facial rash of a 6-year-old boy with JDM; note the rash around his eyes and on his eyelids.

Figure 61.5. The necrotic ulcer on the fingertip of a 14-year-old boy with systemic scleroderma.

Psoriatic Arthritis

Children who have psoriatic arthritis often present a diagnostic challenge. The age ratio favors girls as in polyarticular JIA. The age of onset is bimodal in the early children years and later childhood and adolescence, again like many children with RF negative JIA. The psoriatic rash, which is frequently seen in adult psoriasis early in the course, may not be present at the time of onset of the arthritis in children. The joints are often involved in an asymmetrical, atypical pattern with a predilection for small joints. It is not unusual to have a swollen single peripheral joint such as a finger joint and several swollen toe joints present as well as one or two affected large joints, such as a knee, wrist, or ankle. Nail pitting is occasionally present as well as dactylitis. It is common to have a close relative with psoriasis though the significance of this history is seldom appreciated by the family members. Uveitis is a risk although not as much as seen in oligoarticular or polyarticular JIA. Lab testing may show mild anemia, elevated platelets, and sedimentation rate, and a positive ANA. A skin biopsy to confirm psoriasis may be useful (7).

Enthesitis-Related Arthritis

Children and adolescents can develop a spondyloarthropathy that is revealed over time to be due to ankylosing spondylitis, psoriatic arthritis, inflammatory bowel disease, reactive arthritis, or a seronegative enthesitis and arthritis syndrome. The exact diagnosis may not be evident at initial presentation. Children and adolescents often start with an enthesitis around a joint with inflammation causing swelling, tenderness, and pain at the insertion of a tendon, fascia, or ligament on bone. Lower extremity peripheral arthritis is often present or eventually develops. Back pain, back limitation, chest limitation, and radiographic evidence of sacroiliitis typical of ankylosing spondylitis in adults are seldom seen in the early stage of these diseases in the first two decades of life. Males predominate and age of onset is late childhood to adolescence. Acute uveitis may occur but is not common. Chronic uveitis as seen in other JIA subtypes is rare.

Laboratory testing is not typically helpful in making a diagnosis. Routine testing such as the CBC and sedimentation rate are often normal and the ANA titer is often negative. A positive human leukocyte antigen B27 (HLA-B27) is supportive of an enthesitis-related arthritis but not diagnostic. Radiographic

and MRI of sacroiliac joints are only occasionally abnormal early in the disease course.

Therefore, the diagnosis of the enthesitis-related arthritis is primarily a clinical one. Older childhood and adolescent males with enthesitis who develop lower extremity arthritis may be initially put under the JIA umbrella but are at risk for developing a chronic spondyloarthropathy that continues into adulthood and often require long-term follow-up.

JIA Cardiac Complications

Pericarditis

Pericarditis is the most frequent cardiac complication seen in JIA. The prevalence of pericarditis in JIA ranges from 3% to 9% and it is observed mostly in children with systemic-onset JIA. There is evidence that many clinically active systemic-onset JIA children have silent, clinically insignificant pericardial effusions (6–8).

Symptomatic pericarditis with a pericardial effusion occurs usually at times of systemic disease activity with some combination of fever, rash, and arthritis. These children usually develop acute substernal chest pain and difficulty while breathing, especially when lying flat. The child may complain of referred shoulder, back, or neck pain. They are most comfortable sitting up or leaning forward in bed. The children are tachycardic and may have a friction rub at the lower left sternal border on auscultation of the heart, especially if the pericardial effusion is small to moderate in severity. A chest radiograph shows cardiomegaly. The electrocardiogram shows a predictable series of ST and T wave changes, initially with ST segment elevation, then normalization of ST abnormalities, followed by T wave inversion, and finally a return to baseline ST-T waves. Other electrocardiographic findings include PR depression, which may be diffuse or localized to only a portion of the leads, low voltages, and electrical alternans with large effusions. An echocardiogram (Fig. 61.6) may demonstrate a pericardial effusion that confirms the diagnosis. Occasionally there may be minimal associated pericardial fluid, which does not meet echocardiographic criteria for a pathologic effusion. The diagnosis of pericarditis is made upon clinical grounds, especially if the JIA child has a pattern of pericarditis episodes (6–9).

Fortunately, cardiac tamponade is rare in children with JIA (10–12). The diagnosis of cardiac tamponade is a clinical diagnosis including elevated neck veins with loss of x and y

descents, pulsus paradoxus, tachycardia, and hypotension all of which indicate impaired cardiac output secondary to pericardial fluid impairing ventricular filling (see Chapter 62, Pericardial Diseases/Effusions). Emergent pericardiocentesis is indicated for cardiac tamponade and can be lifesaving.

Bernstein et al. (6) studied 55 patients with JIA and detected 20 patients with pericardial effusions by echocardiography. Sixteen of these twenty children had systemic JIA, four had polyarticular JIA, and none had oligoarticular JIA. Of the 20 patients with abnormal echocardiograms, 9 had an enlarged heart on chest radiograph, 8 had abnormal ECGs and a pericardial friction rub was detected in 4. In 11 of 20 patients with an abnormal echocardiogram, there was no other objective evidence of pericarditis by chest radiograph or electrocardiography.

Gedalia et al. (12) performed echocardiography on 116 children with JIA who were seen consecutively in a JIA clinic. Twenty-six of these children had a pericardial effusion detected, nearly all children with systemic onset JIA. Sixty-one children with systemic onset juvenile idiopathic arthritis (SOJIA) were included in the study. Twenty-one of the sixty-four (34%) had a pericardial effusion with five having large effusions, eight having moderate effusions, and eight having small effusions. All 13 of the children with large and moderate effusions had symptoms while none of the children with small effusions noted had any symptoms. As might be expected, only 1 of 37 children with polyarticular JIA and 3 of oligoarticular JIA children had an effusion. None of these four nonsystemic JIA children had any symptoms with their small effusions.

A more recent study by Alkady et al. (13) utilized newer technology to demonstrate left ventricular abnormalities. The study included 45 children with JIA without cardiac symptoms and 30 age-matched and sex-matched controls. M-mode, 2-D, and pulsed Doppler echocardiography was performed on 36 children with JIA and 30 controls. Tissue Doppler echocardiography (ECHO) was performed on 24 JIA patients to assess systolic and diastolic function of the left ventricle as well as controls. Children with JIA had higher systolic and diastolic blood pressures, resting heart rate, and left ventricular systolic size and volume. Compared to controls, the Doppler ECHO and the tissue Doppler analysis suggested that the JIA group had a lower peak filling capacity, higher peak atrial filling velocity, and prolonged diastolic E and A wave deceleration times and prolonged isovolumic relaxation time.

Myocarditis

Myocarditis is seen rarely in JIA and only in children with active systemic JIA. It can occur by itself or in association with pericarditis. It may result in heart failure and arrhythmias, which may be a fatal complication. Clinically, the child may present with signs of systemic JIA including fever, rash, and arthritis. Cardiac manifestations include tachycardia, hypotension, dyspnea secondary to pulmonary edema, abdominal distention secondary to ascites and poor cardiac output, lower extremity edema in older children and teenagers, cool extremities secondary to poor perfusion and low cardiac output, and feeding intolerance in infants. Diagnostic testing may demonstrate an enlarged heart on chest radiograph, various electrocardiographic changes from nonspecific ST-T wave changes to new bundle branch block or ST changes concerning ischemia (ST elevation or depression, T-wave inversions), and mild elevations in serum troponin levels. The diagnosis of myocarditis is confirmed by echocardiography showing depressed ventricular function, or MRI (Fig. 61.7) showing both depressed ventricular function and/or evidence of patchy mid-myocardial fibrosis on delayed-enhancement imaging.

Bernstein et al. found evidence of myocarditis in only 4 of 40 children while Miller and French (14) noted myocarditis in

Figure 61.6. Delayed enhancement MRI showing patchy mid-myocardial fibrosis in a patient with RA and myocarditis.

Figure 61.7. Echocardiogram from subcostal view showing moderate-sized posterior pericardial effusion in a patient with JIA.

3 of 246 patients. Svantesson et al. (15) noted symptomatic myocarditis in 4 of 320 children with JIA. In a review of the literature, Goldenberg et al. (10) found 4 of 172 children with JIA to have perimyocarditis and 2 to have myocarditis.

Endocarditis

Endocarditis is very rare in JIA and if present at onset requires exclusion of other diagnoses such as rheumatic fever or infectious causes. Aortic and mitral insufficiency have been reported in several patients with systemic onset JIA as well as in RF-positive JIA children years after the JIA diagnosis and tends to occur more in the most severe JIA patients (16–19).

Treatment

Children with JIA who are noted to have asymptomatic pericarditis may be observed and not treated. If treatment appears prudent, nonsteroidal anti-inflammatory drug therapy such as naproxen (15 mg/kg/day in two doses) or indomethacin (1 to 2 mg/kg/day in two doses) are preferable to corticosteroids. Symptomatic pericarditis secondary to JIA warrants corticosteroid therapy. Myocarditis and endocarditis due to JIA are more serious complications than pericarditis and require aggressive corticosteroid therapy.

Corticosteroid therapy should start with a 1- to 3-day course of intravenous methylprednisolone at a dose of 15 to 30 mg/kg/dose per day in a single dose. This aggressive therapy often relieves any pericarditis symptoms and the ECG and echocardiogram return to normal. Occasionally further corticosteroid therapy is needed such as high-dose prednisone at 1 to 2 mg/kg/day for a week with weaning of the drug over the next month depending on the child's response. If the child has systemic JIA, the other clinical features such as fever, rash, and arthritis may have to be considered in the treatment. Methotrexate, anakinra, tocilizumab, and other remissive therapies are often required to control the entire spectrum of clinical problems in systemic JIA children and should be considered when a cardiac complication has occurred. The treatment of myocarditis and endocarditis is similar to the treatment for more severe pericarditis; high-dose corticosteroid treatment with possible remissive therapy. In children with congestive heart failure, angiotensin receptor blockers such as lisinopril are used to improve left ventricular function and reduce ventricular remodeling. In severe ventricular dysfunction with evidence of significantly impaired cardiac output, patients may

require inotropic support with dobutamine, epinephrine, or milrinone. Arrhythmias are rare, but can be life threatening, and may require antiarrhythmic therapy or cardioversion. Rarely, mechanical devices such as intra-aortic balloon pumps or ventricular assist devices may be required to maintain cardiac output until ventricular function improves. In some cases of endocarditis, valve replacement surgery may be needed. The treatment of cardiac tamponade requires an emergency pericardiocentesis to restore adequate cardiac output.

SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is the classic autoimmune rheumatic disease in adults and children. It causes severe constitutional symptoms and may affect multiple organ systems. It is uncommon in children but with its potential disease severity, must be considered in any child with multisystem disease and no obvious infectious or malignant cause.

The incidence of SLE in children and adolescents is low; one study by Malleson et al. (20) estimated an annual incidence rate of 0.36/100,000 in Canadian children. Patients with lupus comprise only 1% to 5% of the children seen in pediatric rheumatology clinics (21,22). Fifteen to seventeen percent of all patients with SLE have their onset in the first two decades of life and many more in the second decade than the first (21,22). Girls develop SLE more than boys. In one study, the onset of lupus in girls under 12 is three times more common than in boys and after 12 years, the girls outnumber the boys by 10:1 (23). SLE is seen in children worldwide. In the United States, SLE does seem to occur more in African-American, Hispanic-American, and Asian-American populations (23,24).

Clinical Patterns for Diagnosis

SLE is a great mimicker and may present in many ways. For example, it can start with arthritis, rash, serositis including pericarditis, nephritis and/or nephrosis, thrombocytopenia or other cytopenias, vasculitis, central nervous system problems such as seizures and psychosis, and other clinical presentations. Diagnosis requires a significantly positive ANA (>1:80) plus at least three of the other criteria of the American College of Rheumatology (ACR) SLE criteria (Table 61.1). Since SLE can have protean presentations, it must be considered in patients who have a systemic illness and no obvious infectious or malignant etiology.

The most common presentation of SLE is with constitutional symptoms and signs. The child may have malaise, fatigue, and fevers. The fevers are not usually high spiking fevers such as seen in systemic JIA but are more often low grade. Rashes such as the classic malar butterfly rash, a palatal rash or ulcerations, and/or vasculitic lesions on the palms and soles are common. Polyarthritis may be present and be indistinguishable from JIA. Other typical lupus signs are buccal ulcerations, hair thinning or alopecia, and Raynaud phenomenon. Less common early signs and symptoms might include chest pain due to pericarditis or pleuritis, hypertension, a photosensitive rash, abdominal pain, chorea, or a peripheral neuropathy. Diagnosis requires awareness both of the common and uncommon ways that SLE may present and knowledge of how to apply the ACR diagnostic criteria in a clinical situation.

Laboratory Testing

The elevated ANA titer test is the *sine qua non* of SLE. The sensitivity is close to 100%. Specificity, though, is a major issue in adults and children. False positives in the normal

population may be between 2% and 30% (25). Rheumatologists often receive consultations for SLE based solely on the presence of an elevated ANA titer. These patients usually do not have SLE as it takes much more than an elevated ANA titer to make the SLE diagnosis (Table 61.1). A positive ANA may be associated with other rheumatic diseases. In children, diseases such as oligoarticular and polyarticular JIA, juvenile dermatomyositis (JDM), mixed connective tissue disease (MCTD) and scleroderma may also have positive ANA titers. Elevated ANA titers may also be associated with viral infections (e.g., Epstein-Barr) as well as exposure to various drugs.

If the child has a positive ANA and has other possible features of SLE such as arthritis or rash, it is prudent to perform more testing. The first test to do is the anti-double stranded DNA (ds-DNA) titer. This test has a very high specificity for SLE, especially with high titers. Its sensitivity is considerably lower as many patients with SLE may have a negative ds-DNA titer at any particular time in the disease course, even at disease onset. It is important to be aware that a negative ds-DNA titer does not exclude a SLE diagnosis (26). A second serologic test to order is anti-Smith (anti-Sm) antibodies. This titer also has a very high specificity for SLE, but like the ds-DNA titer, has a low sensitivity of 10% to 30% (27). A positive antibody titer to the ribonuclear protein (RNP) may be found in 20% to 30% of SLE patients. With high titers, the anti-RNP antibody titer suggests the diagnosis of MCTD, in which the same child may have a mixed clinical picture of SLE, JIA, scleroderma, and myositis during the disease course (28). Antibodies to SS-A and SS-B antigens may also be found in patients with SLE but are more frequently associated with Sjögren syndrome (29–31). These antibodies are also associated with the neonatal lupus syndrome (32–34).

Serologies are essential to the diagnosis of SLE but other more basic testing is also required. The CBC may reveal a normocytic, normochromic anemia of chronic illness or a Coombs positive hemolytic anemia. Patients may also have leucopenia, thrombocytopenia, or lymphopenia. Elevated erythrocyte sedimentation rate, polyclonal hypergammaglobulinemia, and elevated α_2 -globulins are often seen (35). Complement levels C3, C4, and CH50 are frequently decreased but may be normal. Persistently low levels of complement suggest active SLE renal disease (36–38). A urinalysis should be done to check for proteinuria and hematuria, two indicators of active glomerulonephritis. The presence of elevated anti-DNA titers, low complements, and an abnormal urinalysis with proteinuria and/or hematuria confirms the presence of SLE renal disease (39,40). It is also prudent to order a chemistry panel of tests to assess liver and renal function.

A positive RF may be present at low titers in 10% to 30% of children with SLE but if a high titer is found, MCTD must be suspected rather than just SLE. In patients likely to have SLE, the antiphospholipid panel should be performed. This includes an activated partial thromboplastin time (aPTT) and prothrombin time (PT) as well as lupus anticoagulant and anticardiolipin antibodies including the anti-B2 glycoprotein-1.

The above evaluation includes a long list of expensive tests. Care should be taken to perform these tests in a step-wise fashion. The initial screen may include a CBC with a platelet count, sedimentation rate, chemistry panel, urinalysis, C3 and C4, ANA, and ds-DNA. If these tests and the clinical picture suggest a possibility of SLE, then the second group of tests such as anti-Sm, anti-RNP, anti-SS-A, anti-SS-B, lupus anticoagulant and anticardiolipin antibodies should be ordered.

Cardiac Disease in SLE

Cardiac involvement is common in SLE. All layers of the heart may be affected as well as the coronary and pulmonary arteries.

The causes of this cardiac involvement are multifactorial. The inflammatory process of SLE may involve all layers of the heart resulting in pericarditis or myocarditis. Thrombus formation related to both inflammation and the hypercoagulable state associated with SLE may lead to valvular involvement and noninfectious endocarditis. Treatment with corticosteroids and SLE dyslipoproteinemia may accelerate coronary atherosclerosis. Chronic hypertension or uremia may lead to myocardial dysfunction. Cardiac involvement may not be obvious and the clinician must keep a high level of awareness of potential cardiac complications.

Pericarditis

As in JIA, pericarditis is the most common cardiac presentation of SLE, occurring in 20% to 30% of lupus patients (41–43). The clinical presentation of pericarditis related to lupus is identical to any other patient presenting with acute pericarditis including substernal chest pain, difficulty lying flat, or pain with inspiration. The pain is often improved by sitting up and leaning forward. Clinical and diagnostic findings are similar to that seen in other cases of pericarditis including a friction rub, cardiomegaly on chest radiograph and pathologic electrocardiographic changes including ST-T wave changes, PR depression, low voltages and electrical alternans with large effusions. Echocardiogram documents at least some pericardial fluid in most cases. A mild pleural effusion often is seen with the pericardial effusion related to the systemic serositis seen in SLE. Pericardial fluid is often found in many asymptomatic children with active SLE consistent with a systemic serositis (44–46).

The initial presentation of a child with pericarditis of unknown etiology includes an evaluation for SLE. The clinician has to evaluate the child by use of the 11 ACR criteria (Table 61.1). At least four criteria must be present, especially an elevated ANA titer. However, the clinician must also consider other causes of pericarditis including acute rheumatic fever, systemic JIA, Kawasaki disease, MCTD, dermatomyositis, vasculitis diseases such as polyarteritis nodosa (PAN), Wegener granulomatosis, Takayasu arteritis, spondyloarthropathies such as ankylosing spondylitis, and inflammatory bowel disease. Nonrheumatic causes are more likely such as viral pericarditis, bacterial and mycobacterial pericarditis, idiopathic pericarditis, and pericarditis associated with tumors. Anterior chest wall pain in children may mimic the presentation of pericarditis to some extent. These problems include mild problems such as gastrointestinal reflux, costochondritis, and a pain augmentation syndrome. More serious problems such as pleuritis, pneumonia, pneumonitis, pulmonary embolus, myocardial ischemia or infarction, and pulmonary hypertension may present in any lupus patient and mimic symptoms of pericarditis.

Myocardial Involvement

Myocarditis is seen in 15% of children and adolescents with SLE (47). The first sign may be tachycardia even in the absence of fever. As ventricular function deteriorates, the patient may develop signs of volume overload such as poor appetite and ability to eat, abdominal distention/ascites, respiratory distress/pulmonary edema or signs of decreased cardiac output such as hypotension, poor perfusion, and narrowed pulse pressure. Arrhythmias may also develop and be life threatening. Myocarditis due to SLE from other causes of myocarditis is indistinguishable based solely on physical examination and requires further confirmatory testing.

Endocarditis

Libman-Sacks endocarditis (LSE) or noninfectious thrombotic endocarditis is due to SLE involvement of the heart valves

Figure 61.8. Transesophageal echocardiogram showing thickening of the mitral valve with small mobile structures consistent with Liebman-Sacks endocarditis in patient with SLE and transient ischemic attack (TIA).

(48–50). Small nodules accumulate on the supporting structures of the heart valves (Fig. 61.8). These nodules show fibrinoid necrosis and thrombotic material histologically. Involvement of the mitral valve is the most common. A heart murmur may or may not be easily heard. Lesions are typically small and may not result in significant valve destruction. The lesions may or may not be seen by transthoracic echocardiogram. When visualized, the lesions are typically tiny irregular vegetations of 2 to 4 mm in diameter that are seen on the valve itself or on the subvalvular apparatus. However, lesions may be atypical. Galve et al. (51) studied 74 patients with SLE prospectively and found 7 with classic Libman-Sachs lesions but also 8 with atypical lesions. These patients had no nodules but rather had thickening or stiffness of the aortic or mitral valves that led to regurgitation and rarely, stenosis (51). Transesophageal echocardiography is optimal for detection of SLE lesions and new tools such as the real-time 3-D echocardiography may help delineate these lesions further (<video callout>see video 61.1) (52,53). In a prospective study of 342 adults with SLE, LSE was detected by transthoracic echocardiogram (TTE) in 38 patients with 24/38 having mitral valve disease, all 24 with regurgitation, and 9 with stenosis in addition to regurgitation. One patient had mild tricuspid regurgitation (49). In 40 children with SLE, echocardiography noted mitral regurgitation in 4/30, tricuspid regurgitation in 3/40, aortic regurgitation in 2/40, and pulmonary valve involvement in 1/40 (54).

Patients with severe SLE endocarditis may present with congestive heart failure.

It is likely that antiphospholipid antibodies have a role in these endocardial lesions resulting in the layering of thrombotic material on the endocardial surface of the heart and valves.

Other cardiac involvement in patients with SLE includes early atherosclerosis, which may be due to chronic steroid use or primarily to an inflammatory process involving the coronary arteries. Gazarian et al. (55) did an extensive study of childhood SLE coronary artery involvement using echocardiography, thallium perfusion scans, and angiography in children with SLE thought to have normal hearts. Four children had myocardial perfusion scan abnormalities that could be reversed and one child had a fixed myocardial perfusion defect (55). Lipid abnormalities and antiphospholipid antibodies were found in a significant number of the study population. Studies in adults have supported the involvement of the

antiphospholipid antibodies in endocarditis and other cardiac lesions of adult SLE such as intracardiac thrombosis, myocardial disease including coronary artery involvement, microvascular thrombosis, and pulmonary hypertension (56,57). A recent systemic review of the research into the association of antiphospholipid antibodies with valvulopathy in SLE found that 15 of 20 studies demonstrated a positive association between these antibodies and valvular lesions and five studies did not (58).

Treatment of valvular disease in children with SLE will vary. In a child with acute endocarditis, corticosteroids are indicated although the effectiveness of corticosteroids for SLE valvular disease remains unclear. Milder cases may only require the long-term lupus therapy required for other organ systems. Close follow up for cardiac progression, particularly with worsening regurgitation, infective endocarditis, and thromboembolic complications (e.g., stroke) is essential. Valvular disease can also be treated with antiplatelet medication or anticoagulant therapy although there are no large studies looking at antiplatelet therapy versus anticoagulation therapy with warfarin and most data are from small case series or reports (59). Valve replacement may be needed for the most severe SLE endocarditis (60). Children with SLE who have antiphospholipid syndrome and endocarditis require aggressive anticoagulation therapy as well as corticosteroid therapy (61).

Endocarditis in children with SLE is a major concern. Subclinical involvement is common and it is likely that as our tools for detection improve, the degree of pathology found in these patients may increase. Long-term sequelae of this involvement are unknown. Routine echocardiography of children with active SLE appears appropriate, particularly if the patient has antiphospholipid antibodies.

Coronary Artery Involvement and Premature Atherosclerosis in SLE

Children and adolescents as well as adults with SLE may develop significant coronary artery disease with many potential etiologies. Systemic vasculitis or vasculopathy of SLE that affects skin, the gastrointestinal (GI) tract, the brain, and other organs may also target the coronary arteries. Myocardial infarctions have been reported in two young children and in a 17-year old adolescent with SLE (62–64). Giant and smaller diameter coronary aneurysms may develop due to arteritis (65). It is likely that antiphospholipid antibodies play a role in this pathology as well.

The third contributing factor may be premature atherosclerosis. There are several contributors to this increased risk including the high rate of dyslipidemia and hypertension as well as decreased flow-mediated dilation (66,67). Other risk factors reported to be present in adolescents with SLE include the uncontrolled inflammation of SLE, elevated triglycerides, apolipoprotein B, hemoglobin A1C, and insulin levels. Total prednisone dose and low-density lipoprotein cholesterol (LDL-C) levels correlate with the total cholesterol level and may also contribute to premature atherosclerosis (67).

The cardiovascular risk of children and adolescents with SLE is most likely multifactorial and the exact treatment and risk factor modification guidelines for the patients has not yet been well defined.

Conduction System Involvement

Occasionally older children and adolescents with SLE have been reported to develop conduction abnormalities and arrhythmias (68). These conduction problems tend to be mild. Yet AV block, intraventricular conduction problems, and sick sinus syndrome have been described in adults with SLE. Sinus tachycardia, atrial fibrillation, atrial ectopy, and long QT syndrome

have been noted (69). These heart abnormalities may present simply as dizziness or palpitations but also may lead to sudden death. The pathologic causes of these conduction abnormalities are unclear but some authors attribute the defects to the small vessel vasculitis, infiltration of the sinus or AV nodes, myocarditis, or local ischemic injury due to SLE (70).

Pulmonary Hypertension

Pulmonary hypertension (PAH) is unusual in SLE and, if it occurs, may be due to intrinsic lung disease, and not be due to a cardiac etiology (see Chapter 66). Xing et al. (71) reported that by echocardiography, 31 of 299 children age 7 to 18 years with rheumatic disease had pulmonary hypertension. Seventeen of these patients were from a group of 223 SLE children who were tested. These children often presented later in the disease course with shortness of breath or overt heart failure. Children with Raynaud phenomenon and antiphospholipid antibodies were more likely to have more severe pulmonary hypertension. Early detection may require early and routine use of echocardiography and pulmonary function testing with a diffusing capacity (DLCO) testing routine follow-up of children with SLE.

Neonatal lupus erythematosus (NLE) is a transient disease of newborns due to the passive transplacental transfer of maternal antibodies (anti-SS-A [anti-Rho] and anti-SS-B [anti-La]). The quantity of the antibodies, rather than the mere presence of these antibodies, appears to be crucial to NLE tissue damage (72). The newborns primarily present with a rash and congenital heart block (CHB) but may also develop hematologic, liver, kidney, and neurologic findings. Li et al. (73) reported 7 cases in 2011 and reviewed the 94 cases reported in China since 1980. Seventy-three of ninety-four cases had the skin rash, which was seen frequently around the eyes, which also involved other areas of skin. Twenty-three of the ninety-four children had cardiac abnormalities, thirteen with cardiac conduction problems (eight with atrioventricular block [AVB]), and five cases of right bundle branch block. Nine cases had structural defects including five with an atrial septal defect, two with ventricular septal defect, and two with enlarged atria. Forty-four of the ninety-four patients had hematologic changes including 28 with thrombocytopenia, 11 with leukopenia, and 34 with anemia. Thirty cases had hepatic or splenic issues; 28 with an enlarged liver or spleen, 24 with abnormal liver function tests, 6 with splenomegaly, and 4 with cholestasis.

These 94 children had numerous autoantibodies. Eighty-six of 94 had anti-SSA, 51 had anti-SSB, 16 anti-double-stranded DNA, 14 had anti U1-RNP, 13 anti-Sm, 6 anti-RNP, and 4 anti-rRNP.

Of the 94 mothers, 39 had no SLE signs or symptoms and no SLE diagnosis; 35 had definite SLE, 5 had discoid lupus, 3 had Sjögren syndrome, and 4 had miscellaneous autoimmune problems. Eight women developed SLE during their pregnancies. Twenty of the neonates were treated with corticosteroids and four with intravenous immunoglobulin (IVIG). Sixty-eight of the neonatal lupus children had follow-up up to 12 years with 58/68 totally normal at follow up, four still with cardiac abnormalities but improved (two with grade III AVB without pacemaker), and three died (73).

Another recent study of neonatal lupus by Wisuthsarewong et al. (74) reported 17 neonates with NLE who were seen over 15 years at one hospital in Thailand. Skin involvement was found in 70.6% with most having erythematosus patches (91.7%), some having subacute cutaneous LE (50%), 41.7% petechiae, 16.7% persistent cutis marmorata, and 8.3% discoid lesions. Nine cases had CHB and nine had cardiac structural abnormalities.

The heart disease of these neonates must be kept in perspective. Neonatal CHB is rare. But among pregnant women with

SLE, the incidence of neonates with CHB increases dramatically from 1/15,000 births to 1/37 births and if the mother with SLE has anti-SSA antibodies, to 1/13 births. Conversely, the risk of a mother with SLE and these anti-SSA antibodies giving birth to an infant with neonatal lupus is still quite low as 12/13 babies may be normal. If a mother with SLE has one child with neonatal lupus, her risk of having a second neonate with neonatal lupus is much higher at 17% to 49% (75,76).

Noncardiac neonatal lupus is often underappreciated. The incidence of the rash of this disease is variable, ranging from 15% to 70%. Most NLE rashes are photosensitive but some may not be as the rash can be present at birth or develop in non-sun-exposed areas. The rash occurs mostly around the infant's eyes but can be noted anywhere on the body. Liver and spleen involvement occurs without symptoms. Either organ may be mildly enlarged. The liver involvement (15% to 25%) may be reflected in elevated liver enzymes and cholestasis. The liver pathology is similar to neonatal giant cell hepatitis. Neutropenia and thrombocytopenia are the more common hematologic changes. Neurologic abnormalities described include nonspecific white matter changes, calcium deposits in the basal ganglia, hydrocephalus, and blood vessel changes (a vasculopathy). Stippling of the epiphyses may also be found (77).

Prevention of the cardiac damage in NLE is a major concern. Mevorach et al. (78) reviewed a recent report of 95 women who had anti-SSA/Ro antibodies during 98 pregnancies. They performed weekly Doppler echocardiograms and detected 10 fetuses that developed NLE, 3 with first-degree heart block, and 3 with complete heart block. It was difficult to detect the first-degree heart block in these fetuses using echocardiography. A second group studied 70 fetuses of 56 mothers using tissue velocity fetal kinetocardiography for measuring the fetal PR interval. They were able to detect six fetuses with first-degree heart block and treated those infants with fluorinated corticosteroids leading to normalization of atrioventricular (AV) conduction. The rapidity of progression from first-degree to third-degree or complete heart block in these NLE fetuses is cause for concern with development of permanent changes within 2 weeks of a normal sinus rhythm. Early detection with aggressive treatment with corticosteroids or IVIG may be critical (34).

Once born, the neonate with NLE should be evaluated for ongoing active myocarditis and the need for more corticosteroid therapy. Many of the children with complete heart block require pacemakers; however, some patients will resolve their heart block and not require pacemaker placement. The timing of pacemaker placement is critical as transvenous systems cannot be placed until the child is older. In infants requiring pacemaker placement, the procedure is more invasive requiring epicardial placement of the leads with the generator being placed in the abdominal wall. The mortality of these children is high, as much as 20%, due to congestive heart failure, supporting the need for early detection of heart involvement during pregnancy and aggressive treatment of the involved fetus. Any NLE child with cardiac involvement requires close cardiology follow-up to monitoring of ventricular function, for evidence of chronotropic competence, and for hemodynamic compromise related to the conduction disease.

Childhood Takayasu Arteritis (cTA)

Takayasu arteritis (TA) was first described by a Japanese ophthalmologist Dr. Takayasu in 1908 (79) as a pulseless disease. It is now known to be a chronic granulomatous arteritis that affects the large vessels such as the aorta and its major branches. It runs a relapsing and remitting course.

For diagnosis the patient must meet at least three of six American College of Rheumatology criteria for diagnosis. The six diagnostic criteria identified were:

1. Onset before 40 years of age;
2. Angiographic evidence of large arterial vessel disease;
3. A blood pressure differential between any of the limbs of more than 10 mm of Hg;
4. Bruits;
5. Decreased brachial artery pulses;
6. Claudication.

In a prospective validation in adults, this diagnostic scoring system was found to have a sensitivity of 90.5% and a specificity of 97.8% (80,81).

The recently proposed European League Against Rheumatism/Paediatric Rheumatology European Society (EULAR/PReS) European childhood TA criteria are stricter and make angiographic abnormalities in the large arteries as mandatory for the diagnosis. Apart from positive angiographic findings, it also requires one of the other four criteria (blood pressure differential, bruits, decreased brachial pulses, and claudication) for the diagnosis to be made. Apart from the six ACR criteria, these proposed criteria also include hypertension and raised acute phase reactants (82).

Epidemiology: The cTA experience mostly comes from the adult series with a few children as there are only a few published reports on juvenile onset TA. TA appears to be more common in Asian, African, and South American population than in Caucasians. It is mostly a disease of adults but can occur in young adults and children, even very young children. A few illustrative cases in very young children are worth mentioning:

1. A two-year-old child was diagnosed with cTA who presented with congestive cardiac failure and severe aortic stenosis (83).
2. A two-and-a-half-year-old boy was diagnosed with cTA who presented with severe aortic regurgitation and diffuse coronary artery involvement (84).
3. A three-year-old child who presented with severe brain and cardiac involvement and congestive cardiac failure was diagnosed with cTA (85).

In this chapter, TA with age of onset below 18 years is classified as cTA disease. The incidence in childhood is not known. There is a strong female predominance. The disease incidence varies in different geographical areas and the female-to-male ratio, clinical course, disease of onset, and organs involved also vary by geographic location. The cause for these geographical variations is not known (86). Japanese patients had more ascending aorta and coronary-cardiac involvement while Indian patients had more involvement of descending aorta and renal artery involvement. A role of gender in these variations was postulated in some Indian studies as the males were found to have significantly higher incidence of aortic arch and coronary disease while females had more of abdominal aorta and renal artery disease (86,87). Valentini et al. reported a mother and a child who were both diagnosed with TA. Based on the human leukocyte antigen (HLA) typing of the mother and daughter, they suggested a possible familial component and a possible association with type I diabetes mellitus (insulin-dependent diabetes mellitus [IDDM]) gene (88). Similar findings have been described by other researchers in familial occurrences of TA (89–91). On the other hand, Makino et al. (92) reported dissimilar HLA findings in the two siblings who were diagnosed with TA. An association between TA and the HLA Bw52 has been recognized in the patients from Japan and Mexico (93,94). Jeeva et al. in 2007 (95) reported a Pakistani family with five out of seven siblings between the ages of 12 to 19 years who developed TA. Based on their genetic studies and HLA typing, Jeeva et al. (95) speculated the possibility of autosomal recessive inheritance for that family.

Like adults, children with cTA present with very nonspecific initial symptoms that are mostly constitutional, such as

Figure 61.9. MRA of aorta in patient with TA. Note the irregularity of the aortic wall.

fever, arthralgia, headaches, palpitations, and abdominal pain (96). Compared to adults, Jales-Neto et al. (97) reported a worse prognosis in juvenile onset TA. In their series of 62 TA patients (17 juvenile onset and 45 adult onset), they suggested that juvenile onset TA more often had a specific type of renovascular involvement in which they were more likely to have aneurysms (Fig. 61.9). Their disease was more refractory to treatment as compared to their adult counterparts (97). In contrast, the cardiac involvement and cardiac prognosis between the two groups were similar (97).

Case series of TA: The largest, predominantly juvenile onset, TA series are reported from India, South Africa, Korea, and Belgium. The Indian series was a longitudinal 16-year follow-up of 106 patients with Takayasu disease. The mean age of onset was 27 years (± 9 years) with a 1:1.6 M:F ratio. The most common presentation was hypertension (77.4%); 12.3% patients had congestive cardiac failure. They were treated by antihypertensive drugs therapy (76.4%), antitubercular drugs (7.5%), steroids (15%), and cyclophosphamide in one patient. Four percent of patients had coronary angiography (98).

Sharma et al. (99) reported another Indian series of 83 patients with TA in 1992. The age range at diagnosis was between 5 to 53 years (mean 26.9 ± 9.7) with a similar male to female ratio. The clinical presentation and disease course was similar to the previous series of 106 patients. Muranjan et al. (100) reported 17 children with TA in the age range between 5 and 11 years (M:F = 1.1:1). In this series, the main presenting signs were hypertension (64.7%), congestive cardiac failure (47%), cardiomyopathy (41.1%), and cardiac valvular disease (35.2%).

Nineteen children with cTA were reported from Turkey (101) in 2008. The male to female ratio in this cohort was 1:2.8. The age range at diagnosis was between 8 and 17 years (mean 12.84 ± 2.69 years, median 13 years). The most common clinical finding was hypertension. Hong et al. (102) reported cTA in 70 Korean children. The male-to-female ratio was 1:4.4 and the youngest patient was a 3-year-old female. The most common manifestation was hypertension (93%) and

several of these children also had congestive cardiac failure. None was reported to have coronary artery involvement. Orea Tejada et al. (103) looked specifically at cardiac damage in 125 patients from a mixed age group cohort from Spain. In their series, cardiac damage was identified in a high percentage of patients (82.4%). The cardiac involvement included; precordial murmurs in 65%, cardiomegaly in 70%, congestive cardiac failure in 28%, angina in 13.6%, an abnormal electrocardiogram (EKG) in 60%, left ventricular hypertrophy in 40.8%, right ventricular hypertrophy in 8.8%, and conduction defects in 12%. Aortic regurgitation was diagnosed in 11.2% of patients and mitral valve regurgitation was diagnosed in 13.6% of cases due to left ventricular dilation. In their series, 4.8% patients died due to cardiac damage and congestive cardiac failure. Seguchi et al. (104) reported a 11-year old girl who had developed ostial stenosis of left coronary artery as the only manifestation of Takayasu arteritis. Emi et al. (105) reported both coronary ostial stenosis as a sole manifestation of TA. Also, left ventricular submitral aneurysms have been described in children with TA (105–107).

Coronary artery involvement in the mixed age cohort is reported to be present in 9% to 10% of the patients with TA (108–110). Matsubara et al. divided coronary artery lesions based on the pathologic findings into three categories; (i) involvement of the ostia and initial part of the coronary artery; (ii) coronary arteries with patchy and segmental disease as well as a more generally diffuse and wide spread coronary artery involvement; (iii) coronary aneurysms present (Fig. 61.10). They suggested that most of the lesions in TA belong in category one and are the result of extension of inflammation from the aortic root in the form of intimal proliferation and fibrosis of the media and adventitia in the coronary arteries (108,111). Category two lesions are due to coronary arteritis. These lesions have a predilection for the proximal part of coronary arteries though this involvement can be more generalized and diffuse in distribution. The third category with a coronary artery aneurysm was less common in their series (108). Due to these coronary lesions, TA should be suspected in differential diagnosis of a young Asian female with angina.

Figure 61.10. Coronary angiogram showing multiple small coronary artery saccular aneurysms in a patient with chest pain and vasculitis.

If required, surgical treatment should be performed when TA is in an inactive state. If an operation must be performed in active (histologically or clinically) TA, postoperative corticosteroids should always be given (112). Several procedures such as transaortic endarterectomy, coronary revascularization with vein grafts, and aortocoronary bypass surgery have been used successfully in patients who require surgery (113–115).

Pathology findings: Sharma et al. (116) described autopsy findings from 10 children with TA. In the series, cardiac involvement included left ventricular hypertrophy (nine), right ventricular hypertrophy (four), biventricular hypertrophy (three), myocarditis (two), and involvement of coronary artery (one). The authors concluded that the most common cause of mortality is severe hypertension and its effect on heart, kidneys, and brain. These problems appeared to be worsened by delay in diagnosis. In 12.5% of their autopsy findings from patients with TA, Rose et al. (117) reported the unusual autopsy findings of segments of narrowing and dilation of major epicardial coronary arteries with coronary aneurysm formation. In another autopsy series from India, Kinare et al. compared cardiac findings from pediatric patients ($n = 25$) and adults ($n = 35$). They reported that the heart was normal in autopsy in 20.5% of the adult patients, but the heart was normal in only 8.7% of pediatric patients. Renal and aortic stenosis was present in 91.3% of pediatric and 80.0% of adult patients. Congestive heart failure was more common in pediatric age group (68%) (118).

Associations

Several studies have reported association of many autoimmune diseases with TA, such as SLE (119–122), ankylosing spondylitis (92,123), JIA (124–126), anterior uveitis (127,128), sarcoidosis (129), seronegative spondyloarthropathy (130), Crohn disease (131), Wegener granulomatosis (132), Sweet syndrome (133,134), ulcerative colitis (135), and Wiskott-Aldrich syndrome (136). Interestingly, an association between rheumatic heart disease and TA has been found and a few reports comment on cardiac involvement due to both diseases at the same time (103).

Tuberculosis and TA

The Mantoux test was strongly positive in most patients from many series, especially those reported from India and South Africa. The tuberculin test and quantiferon gold was also significantly positive for their cohort in the patients reported from Europe. Yet the relationship with mycobacterium tuberculosis is still speculative. Some have suggested that TA patients show accelerated immune response to mycobacterium tuberculosis antigens, specifically its 65 kDa HSP (65 kDa heat shock protein). Several authors suggest a role of mycobacterium tuberculosis in the immunogenesis of TA (137–141).

Delay in Diagnosis

Common findings in all the published reports and series were that the time between the onset of symptoms and diagnosis was long (mostly in months and few in years). The delay may be due to several reasons including rarity of this diagnosis, absence of characteristic symptoms, incidence in the countries with less robust investigational facilities, and comorbidities with similar symptoms (142,143).

Clinical Manifestations of cTA

The most common manifestation in all series is hypertension. Other symptoms are secondary to congestive heart failure, ischemic symptoms due to aortic and coronary involvement, and renal artery involvement (144). Thomas et al. (110)

reported 86 children with TA in their series of 1,130 cases of Takayasu disease. Out of these 86 patients, 5% were treated for angina and myocardial infarction. Aortic valve involvement is usually associated with arterial involvement of other large vessels but can occur alone. Aortic root dilation causing valve regurgitation is common in cTA. It is also associated with coronary ostial involvement in 30% of cases and when accompanied with coronary artery disease can cause sudden death (145). It has been suggested that coronary angiography should be performed before operative treatment of aortic valve and early treatment of aortic disease could be lifesaving (146). The symptoms of myocardial ischemia or hypertension along with raised inflammatory markers in a young female should prompt for investigations for TA (147). Mitral valve involvement has also been reported in TA. Some other cardiac complications in cTA are aortic pseudoaneurysms (148), dissection of the aorta (149), and dilated cardiomyopathy (150).

Diagnostic Modalities

Routine labs for inflammatory markers and organ-specific investigations such as EKG and echocardiography are done first. Conventional angiography is considered the gold standard in TA and cTA. It generally agreed that only conventional angiography gives information on the lumen of the artery and may often be needed despite its invasiveness. Recently, less invasive investigations such as computed tomographic angiography (CTA) and gadolinium-enhanced 3-D magnetic resonance angiography (MRA) have been used more as they are increasingly useful in delineating the initial arterial wall changes such as arterial wall thickening (151–153).

Treatment

Corticosteroids, methotrexate, mycophenolate, azathioprine, total lymphoid irradiation (TLI), cyclophosphamide, and biologic therapies such as TNF- α blocking agents are treatment options. Mortality reduction with prednisone or methylprednisolone treatment has not been firmly established. Cyclophosphamide and mycophenolate are the most commonly used remittive agents. Sildenafil has been used in cTA to treat extremity ischemia (154).

Polyarteritis Nodosa

PAN was first described in 1866 by Kussmaul and Maier (155,156). PAN is an uncommon condition in pediatric age group. It is of two types, the cutaneous PAN and systemic PAN. This discussion focuses on the systemic PAN that can affect the heart. It is a peri nuclear antineutrophil cytoplasmic antibodies (p-ANCA) positive vasculitis of small and medium vessels and has predilection to involve bifurcations of blood vessel. The cause for this behavior is not clear but it is presumed to be related to turbulence-mediated injury initiating the inflammation at bifurcations. The vasculitis is typically patchy in nature and is characterized by endothelial proliferation, fibrinoid necrosis, microthrombi, and resulting ischemia damage to vessel and microaneurysm formation. Rupture or thrombosis of these microaneurysms can lead to organ ischemia and damage, intraperitoneal bleeds, and perirenal hematoma (157–160).

In systemic PAN, the most commonly involved organs are skin, joints, peripheral nerves, gut, scrotum, and kidneys, while lungs are usually spared (161). The cardiac, neurologic, and respiratory manifestations have been reported in children but are less frequent (158,162–167). In adults with PAN, the incidence of these involvements is up to 86% while in children it is between 0% and 85% reported in most published series (168,169). A familial Mediterranean Fever (FMF) gene has been found significantly more often in patients with PAN and vice versa (170–173), especially in the geographical areas

around Turkey and Israel. There has also been an association of PAN with hepatitis B infection (173,174). There is no evidence that children with these associations have a higher incidence of cardiac complications or involvement. Ozen et al. examined a cohort of 17 patients who had both PAN and FMF. They reported that when both conditions occurred, the PAN onset was at a younger age. When compared to patients with PAN alone, these children were less severely involved, including cardiac complications, had a better overall prognosis, and tended to respond better to steroid treatment. In contrast, the incidence of perirenal hematomas was higher in the PAN/FMF children compared to patients with only PAN. Several other workers have confirmed this finding (162,170,171,175–177). Cardiac involvement was not found in any of their cohorts of PAN/FMF patients. Though cardiac involvement is rare in PAN patients with FMF, there is not enough evidence to say that these genes together are protective for cardiac involvement.

Cardiac involvement in PAN is reported to be a bad prognostic factor (178–180). Gunwale et al. reported 15 cases of PAN with systemic involvement, between 4 and 14 years of age. The most common finding in their cohort was diminished left ventricular systolic function and atrioventricular valve regurgitation (mitral and tricuspid), even in asymptomatic patients. One patient had some pericardial thickening without effusion. The EKGs of these patients did not show any evidence of myocardial ischemia, infarction, or conduction defects (169).

Infantile polyarteritis nodosa is a systemic vasculitis that occurs below two years of age. Though multiple organs can be involved, it mainly affects the central nervous system and the heart. It shares some clinicopathologic features with Kawasaki disease (181,182). Some have questioned whether these two are the same disease. The diagnosis has usually been made postmortem because of the rarity of the disease and on occasion, the overwhelmingly acute presentation without an easy diagnosis. Munro et al. (183) described a fatal case of late onset enterocolitis in a 3-month-old infant who died after 3 weeks of enterocolitis onset. The postmortem findings were consistent with systemic arteritis including the coronary arteries and a probable diagnosis of Infantile PAN was made. Edwin et al. reported (184) two cases of pericardial hemorrhage in both a 9-month-old child and a 5-year-old child. Both died of cardiac tamponade with the diagnosis of PAN established on autopsy. The fact that the diagnosis of PAN in children may be established at autopsy has not changed over the years, especially when it presents in infants and when coronary arteries are involved (184–189). Surprisingly, PAN in these infants presented as an acute illness starting with symptoms of upper respiratory infection or gastroenteritis. Munro-Faure (190), examined 19 fatal cases of predominantly infantile coronary arteritis. Triggers such as Streptococcal infection, Coxsackie B virus, and exposure to antibiotics such as sulfa, were hypothesized as possible etiologic factors without any conclusive evidence.

MRI, CT, CTA, and Tc-99m dimercaptosuccinic acid (DMSA) renal scan have been used successfully as noninvasive methods to investigate arteritis and aneurysms of different organ systems (191,192). These methods have not been very useful in the past for investigating cardiac and coronary artery involvement. Kobayashi et al. (193) did recently report a more successful use of MRI of the heart to detect coronary artery ectasies and aneurysm. EKG and echocardiography are commonly performed but are less often revealing.

Lab findings include mild anemia and increased inflammatory markers (C-reactive protein [CRP], erythrocyte sedimentation rate [ESR], WBC, platelets and immunoglobulin). Myocardial enzymes such as the creatine kinase (CK) may increase indicating myocardial damage. ANCA are an important part of lab investigations in adults with PAN as opposed

to children with PAN who are mostly negative to this antibody (194). Other tests such as myeloperoxidase (MPO)-ANCA or proteinase 3 (PR3)-ANCA, are also negative in children and are not helpful in making the PAN diagnosis (194). The ANA is usually negative (195). The serum neopterin, factor VIII antigen and other markers of endothelial injury or repair may be elevated. Some have examined the use of endothelial microparticles (EMP) and platelet microparticles (PMP) as surrogate markers for endothelial injury (195–199).

Coronary angiography can delineate vessel aneurysms and ectasias. Other angiography may help with the definitive diagnosis of PAN. Brogan and Dillon (196) have suggested several nonaneurysmal features of visceral angiograms in PAN that are more commonly found than aneurysms and contribute to making the diagnosis. These signs are delayed emptying of small arteries, perfusion defects, and the presence of collateral arteries. Whether these nonaneurysmal findings could be useful increasing sensitivity of cardiac lesions is not known.

Biopsy and tissue sampling may be an option for diagnosis mostly when evaluating the visceral organs. Its utility in cardiac involvement has not been proven so far. Also the patchy and irregular distribution of PAN lesions and the risk of the procedure make it a less attractive diagnostic tool. The right combination of the clinical pattern, laboratory testing, and imaging are needed for the diagnosis of PAN with cardiac complications.

No randomized controlled trials are available to guide the therapy in PAN with cardiac disease. The information available is from experience-based published literature. High-dose corticosteroids still remain the mainstay of treatment especially in infantile PAN. Depending upon the severity of the disease, corticosteroids may be initiated by using initial boluses of methylprednisolone 15 to 30 mg/kg/dose (maximum of 1 gm.) for three to five consecutive days followed by oral prednisone/prednisolone at a dose of 1 to 2 mg/kg/day for 4 to 6 weeks. The dose can then be tapered over a variable period of time depending on the response (195,200–203). Others have used alternate day steroid therapy (195). The new strategies for treatment include using oral or intravenous cyclophosphamide (2 mg/kg/day or 500 to 1000 mg IV/M²) with steroids as induction therapy with dose corrections for renal or hepatic diseases as required. Cyclophosphamide IV is used on monthly basis for a period of 6 months for better compliance but it is claimed that oral regimen has better efficacy than IV bolus dose. After induction is achieved, several other agents can be used alone or in combination with steroids depending on the severity of disease and response to treatment for a further period of approximately one and a half years (202,204). These agents include azathioprine, methotrexate, and mycophenolate mofetil. There is no evidence that one agent is better than another for maintenance therapy. Intravenous immunoglobulin and plasma exchange has been used in emergency situations while waiting for other immunosuppressants to have an effect (205–209). A word of caution about use of IVIG as occasionally it can lead to ANCA positivity in otherwise ANCA negative patients (210). Anecdotal case reports of successful use of infliximab and rituximab in resistant cases have been recently published (211–215). Autologous stem cell transplant may be considered as an ultimate option keeping risk benefit in mind (216–219).

Hepatitis B-associated PAN cannot be treated by above regimens because of the possible flare up of the hepatitis virus and consequent liver damage. Intravenous immunoglobulin can still be used as rescue therapy and to facilitate immune complex removal. Steroids are used with antiviral therapy to induce remission under strict monitoring because these patients run a risk of acute fulminant hepatitis with liver failure. The steroid and antiviral therapies have been successfully used in combination with plasma exchange. After remission is achieved, only

antivirals are continued if needed and hepatitis B is allowed to undergo its seroconversion. There is evidence that patients who achieved seroconversion had a 0% relapse rate (174,220–223). Antiplatelet therapy with aspirin or clopidogrel is recommended in all cases as an adjuvant therapy (203).

Behçet Disease

In 1837, Dr. Huluci Behçets a Turkish dermatologist, first described the disease in three patients (224). Initially it was thought to be more prevalent near the old silk trading routes in the Middle East and in Central Asia and was called the Silk Road Disease. Behçet disease (BD) shows geographic and ethnic preferences as well as differences in disease course and outcomes (225,226). It is more common in Japan, Turkey, and Middle East compared to rest of the world (227). There is high frequency of familial cases especially in pediatric patients (228,229).

BD is a systemic vasculitis syndrome that affects all sizes of arteries as well as veins, both superficial and deep. It involves several organs such as central nervous system, gastrointestinal, skin, mucous membranes, eyes, and musculoskeletal system. Atzeni et al. (230) have reported cardiac involvement in 7% to 46% of adults with BD and 20% of those involved died due to their cardiac complications. Cardiac involvement in pediatric patients with BD is not common (227,229,231–233). Koné-Paut et al. (228) examined 86 pediatric BD retrospectively from Turkey, France, Iran, and Saudi Arabia in 1998. None of the patients in their cohort were found to have cardiac disease. Davatchi et al. (234) reported 0.6% cardiac involvement in their large cohort of 6,500 pediatric and adult patients with BD in Iran who were followed for as long as 35 years.

BD has been found to have association with HLA B51 (B51 is a split antigen of antigen B5) and HLA B27. It has been observed that patients who are positive for either or both genes have milder disease (235,236). On the other hand, Zouboulis et al. (232) found HLA-B5 gene positivity a marker of severe BD. Abdolhadi et al. (237) reported that HLA B27 positive patients with BD had a higher incidence of ankylosing spondylitis, chronic diarrhea, and type III or IV (WHO classification) glomerulonephritis, compared to HLA B27 negative patients. An association between FMF and BD has also been recognized (238–240). None of these associations has been reported to increase risk for cardiac complications in patients with BD.

There is no published literature on the incidence of cardiac complications in pediatric patients with BD. In BD adults, multiple cardiac complications can include; interatrial septum aneurysm, mitral valve prolapse, mitral regurgitation, aneurysmal dilatations of sinus of Valsalva and ascending aorta, coronary artery aneurysm, cardiac thrombus, myocarditis, and conduction disturbances (241). Most of these patients developed cardiac problems at an early adult age. It is not known whether their cardiac involvement started at an early age such as during adolescence. The average time between the oral ulceration and initial symptoms of BD to that of a second major manifestation has been estimated to be 8.8 years (242).

Anecdotal reports have described other cardiac problems such as endomyocardial fibrosis, noninfective endocarditis, aneurysms of the ascending aorta, intracardiac thrombus formation, coronary artery aneurysm, and pulmonary artery aneurysms (243–246). All of these patients responded to immunosuppressive therapy and recovered without residua. Coronary artery bypass and heart transplant in pediatric BD has also been reported (245,247). The posttransplant survival was only 1 year. Recurrence of the aneurysmal disease, hypercoagulable state, thrombosis, and the tendency for an exaggerated inflammatory response (pathergy) were major drawbacks reported with the procedure.

Zhuang et al. (248) reported myocardial infarction and aneurysm of the left ascending coronary artery in a 12-year-old boy in Turkey who responded well to urokinase, corticosteroids, colchicine, and aspirin.

Juvenile Dermatomyositis

The exact prevalence of cardiac complications in JDM is not known (249). Cardiac complications appear to be unusual in JDM. On the other hand, cardiac involvement may have been underinvestigated in children and that may in part be contributing to the reported low prevalence of cardiac complications in JDM. The most common cardiac finding is sinus tachycardia. Subtle conduction defects with the tachycardia are also reported. Karaca et al. (249) reported sinus bradycardia in a 11-year-old due to sinus node involvement in JDM who recovered after his myositis inflammation was treated without requiring any specific treatment for bradycardia. Severe conduction abnormalities are rare, for example, complete heart block resulting in congestive cardiac failure (250).

Sato et al. (251,252) identified anti-CADM-140 antibodies exclusively in 8 clinically amyopathic patients out of total 42 patients with JDM. Their data suggested that these amyopathic patients had significant and progressive interstitial lung disease and cardiac complications when compared to other JDM patients who did not have anti-CADM-140 antibodies (50% vs. 6%; $p = 0.008$).

Coronary artery disease has been reported. In some cases, this vasculitis appears to cause myocardial damage due to the combination of small vessel vasculitis of myocardial vessels, coronary artery involvement, and/or cytokine-induced myocarditis (250). Myocardial involvement is more commonly reported in adult dermatomyositis and in polymyositis (253–259). In adults, cardiac complications are the cause of death in 10%–20% of patients with adult dermatomyositis and polymyositis (250,260). Some have reported an association between heart complications and antisignal recognition particle myositis-specific autoantibodies in patients with JDM. A significant correlation was found between degree of myonecrosis as measured by muscle enzymes and the levels of antisignal recognition particle myositis-specific autoantibodies (261,262). Constantin et al. (263) compared cardiac complications among several other parameters between 66 adult dermatomyositis and 44 JDM patients using the Hungarian National Registry of patients with dermatomyositis. They did not find any evidence of cardiac involvement in JDM.

Schwartz et al. (264) performed a detailed cardiac examination including echocardiography, early diastolic transmitral flow/early diastolic tissue velocity (E/E') as a marker for diastolic dysfunction, 12-channel ECG and physical examination on 59 JDM patients and 59 age-matched and sex-matched controls. They reported that E/E' was elevated in 13 (22%) patients versus 0 controls ($p < 0.001$). In their series, 10 JDM patients presented with abnormal ECG as compared to only 4 in controls group ($p = 0.054$). It can be argued that if hypertension has a role in these cardiac findings, it may be in part due to corticosteroid therapy (265).

Scleroderma

Heine et al. (266) described cardiac involvement in scleroderma for the first time. In 1943, Weiss et al. (267) confirmed the findings of Heine and also identified cardiac fibrosis as the case of cardiac failure in systemic scleroderma patients. Systemic scleroderma with internal organ involvement is a rare disease in childhood and occurs less commonly than local scleroderma diseases such as linear scleroderma and morphea (268,269). The prognosis and mortality in juvenile onset systemic disease is, in general, better than adult onset disease

(270). Yet, in those children with severe or fatal scleroderma, disease progression and mortality may be more difficult to prevent (268,271–273).

The most common cause of death in these children is cardiopulmonary disease. The cardiac involvement in systemic scleroderma can be primarily due to the scleroderma disease process or secondary to severe lung involvement. Pulmonary involvement is the most common systemic organ affected by scleroderma (75% patients) and cardiac involvement alone is rare (1%) but a mixed picture of cardiopulmonary involvement is the most common cause of death in systemic scleroderma (272,274,275). Some reports have suggested that a few children with localized scleroderma have not only skin disease but may develop systemic, eye and central nervous system (CNS) involvement (275–277). These patients who evolve and develop extracutaneous disease appear to have a higher prevalence of antinuclear antibodies with a homogeneous pattern and a positive RF.

Quartier et al. (278) have described ischemic cardiac injuries and dilated cardiomyopathy in three children with systemic scleroderma. Of these three children, two died and one survived after cardiac transplant. The authors also believed that treatment with corticosteroids, methotrexate, and cyclosporin were effective on muscle, skin, and lung involvement but did not stop progression of esophageal or myocardial dysfunction (278). Most believe that patients who also had polymyositis with skeletal muscle involvement in addition to their scleroderma are more at risk for cardiac involvement and congestive cardiac failure (278–280). Some primary autoimmune myocardial inflammation is also considered as a small factor contributing to myocardial damage and fibrosis. The cardiac ischemic injuries are more common than that of cardiomyopathy.

Myocardial fibrosis is reported to be the most common autopsy finding in fatal cases of juvenile systemic sclerosis (279) and myocardial fibrosis is considered as a hallmark of cardiac involvement in systemic scleroderma. The myocardial fibrosis in scleroderma is histologically different from that due to atherosclerotic coronary artery disease. Fibrosis in scleroderma involves mainly the subendocardial layer of the heart that is spared in atherosclerosis and myocardial hemosiderin deposits that are found in atherosclerotic disease are absent in the myocardium of patients with systemic sclerosis. What this means from a therapeutic point of view is not yet clear (281–283,284–287).

Cardiac ischemic disease may result due to several causes such as restrictive pulmonary disease, coronary artery involvement, myocardial microvasculitis causing perfusion defects, impaired repair mechanism, and sclerosis. Raynaud phenomenon is very common in patients with scleroderma, and Raynaud equivalent vascular phenomenon in cardiac vessels and coronary arteries of these patients leads to repeated cardiac ischemia and myocardial fibrosis (288,289). Systemic vascular disease leading to systemic hypertension and renal crisis can also affect cardiac perfusion adversely and lead to left ventricular failure (280). Scleroderma may also present initially as pericardial disease or conduction abnormalities secondary to myocardial involvement.

The most common symptom due to myocardial involvement in juvenile scleroderma is dyspnea and reduced exercise tolerance. The symptoms of myocardial ischemic pain, angina, and right or left heart failure may develop depending on the mechanism and region of the myocardium that is affected.

The prevalence of the anti-Scl 70 antibody is rare in juvenile onset disease, with or without extracutaneous manifestations (276). The disease-specific autoantibody profile is not diagnostic and clinically useful in juvenile scleroderma. Serum anti-PM-Scl and anti-U1RNP antibodies are more frequently positive in juvenile onset disease while the anti-RNA polymerase III and anticentromere antibodies are more frequently positive in adult

onset disease (270). Apart from conventional studies such as lab tests, echocardiography, and EKG, other modalities, that is, thallium scintigraphy, single photon emission computed tomography (SPECT), and MRI have been utilized to estimate the prevalence of asymptomatic cardiac involvement. In adult series, the prevalence of cardiac disease was estimated to be around 69%. The prevalence of asymptomatic cardiac disease in children with systemic sclerosis is not known (289–294).

Unfortunately, there are not many investigative studies in the literature that provide more information on the cardiac risks and risk factor associations in juvenile onset systemic scleroderma. Endomyocardial biopsy is neither a risk-free procedure nor is it used very often in practice. The available information on cardiac involvement mostly comes from autopsy results that only represent the extreme end of the spectrum of the disease. It appears that while the cardiac involvement is not common in juvenile onset scleroderma, its presence suggests a poor prognosis. The prevalence of asymptomatic cardiac involvement in childhood systemic scleroderma is not known. It is in the best interest of the patient to investigate for cardiac involvement early with echocardiography or MRI and on a regular basis thereafter. Early and aggressive therapy with immunosuppressant medication, fibrinolytic medication, and supportive therapy may help to prevent cardiac disease and improve the outcome in patients with juvenile onset systemic scleroderma. It is also important to monitor children with local scleroderma for systemic disease.

Sarcoidosis

Bernstein et al. (295,296) described cardiac involvement for the first time in an autopsy of a sarcoidosis patient in 1929. Since

then, it is increasingly recognized that the incidence of cardiac sarcoidosis is far more common than previously thought. When it does occur, cardiac involvement in sarcoidosis is still often overlooked due to the lack of awareness of its possibility, its slow subclinical progression, and the absence of any robust and reliable diagnostic tool (297). Cardiac involvement in children and adults appears to be unusual in most areas of the world, but for unexplained reasons it is far higher in Japanese population than the rest of the world, affecting up to 50% to 78% of sarcoidosis patients. In Japanese patients, 85% of deaths with sarcoidosis are due to cardiac involvement (298–300).

Hoffmann et al. (301) studied 48 children in Denmark with pediatric sarcoidosis (ages <15 years). They reported that clinical features and presentations in their cohort were similar to that of adults but they found cardiac involvement to be more frequent in younger patients and adolescents than in adults (302–306). There are conflicting opinions regarding its prognostic significance. Several groups report that the significance of cardiac involvement from prognostic point of view is not known (195) while other groups believe it to be potentially fatal and a bad prognostic sign (296,298,307–309).

Most studies and reports are from the mixed age population of patients. Silverman et al. (310) reported autopsy findings in 84 sarcoidosis patients in 1978. These patients ranged from 18 to 80 years with a male to female ratio of 1:1.5. Of these patients, 27% were found to have cardiac granulomas. Of the patients who were found to have cardiac involvement, 35% did not have cardiac symptoms while there was a history of heart failure, arrhythmias, and/or conduction defects in 65%. Similar findings have been reported by others who note that the most common site for granulomas was the left ventricular

TABLE 61.2 Updated Guideline for Diagnosis of Cardiac Sarcoidosis by the Japanese Ministry of Health and Welfare in 2006	
Histologic diagnosis group	
Cardiac sarcoidosis is confirmed when endomyocardial biopsy specimens demonstrate noncaseating epithelioid cell granulomas with histologic or clinical diagnosis of extracardiac sarcoidosis.	
Clinical diagnosis group	
If endomyocardial biopsy specimens do not demonstrate noncaseating epithelioid cell granulomas, extracardiac sarcoidosis is diagnosed histologically or clinically if the disease satisfies the following conditions and more than one in six basic diagnostic criteria are present.	
1. Two or more of the four major criteria are satisfied.	
2. One in four of the major criteria and two or more of the five minor criteria are satisfied.	
Major criteria	
1. Advanced AVB.	
2. Basal thinning of the interventricular septum.	
3. Positive 67 gallium uptake in the heart.	
4. Depressed ejection fraction of the left ventricle (<50%).	
Minor criteria	
Abnormal ECG findings: ventricular arrhythmias (ventricular tachycardia, multifocal or frequent PVCs), CRBBB, axis deviation or abnormal Q-wave.	
Abnormal echocardiography: regional abnormal wall motion or morphologic abnormality (ventricular aneurysm, wall thickening).	
Nuclear medicine: perfusion defect detected by 201 thallium or 99 m technetium myocardial scintigraphy.	
Gadolinium-enhanced CMR imaging: delayed myocardial enhancement	
Endomyocardial biopsy: interstitial fibrosis or monocyte infiltration over moderate grade.	

CMR, cardiac magnetic resonance; CRBBB, complete right bundle branch block; ECG, electrocardiogram; PVC, premature ventricular contraction
From Tahara N, et al. Heterogeneous myocardial FDG uptake and the disease activity in cardiac sarcoidosis. *JACC Cardiovasc Imaging* 2010;3:1219–1228. Ref. 322.

free wall, followed by the interventricular septum, papillary muscles, right ventricular and atrial, and lastly, aortic arch (307,311,312). Sarcoidosis can affect the pericardium, myocardium, or endocardium with equal frequency (296,313).

These autopsy findings support recent clinical findings that the real incidence of clinical cardiac involvement in sarcoidosis may be between 5% and 50% (314). Cardiac disease is not necessarily always secondary to cor pulmonale or lung involvement as previously thought but isolated cardiac involvement can occur at any age and stage of the disease (296,314) in the absence of pulmonary and even any other systemic involvement. Sometimes cardiac involvement only got attention of physicians after the pulmonary disease resolved (315). Occasionally cardiac involvement may be the first presentation of the disease (306). The severity and duration of pulmonary disease cannot predict the presence and extent of cardiac involvement (316).

Diagnosis of the cardiac involvement may be problematic (Table 61.2). As an initial screening test, 12-lead EKG, especially the 24-hour Holter monitoring, and/or postexercise EKGs are very cost-effective tests. Echocardiography is recommended to diagnose the cardiac involvement in patients with sarcoidosis. Echocardiography may be useful if it demonstrates a classic basal interventricular septal thinning or localized ventricular aneurysmal dilation, usually without coronary artery disease. (317–319). Myocardial biopsies have a poor diagnostic yield (<20% to 30%) as the sarcoidosis disease involvement is patchy and most biopsies are performed on the right side of heart (311,312,320). Cardiac MRI with gadolinium enhancement and positron emission tomography (PET) scanning are also good investigational tools to diagnose and evaluate cardiac involvement (319,321). (See summary of testing in Table 61.1)

The most common symptoms due to cardiac involvement in sarcoidosis include cardiac arrhythmias and conduction defects. Sudden death has been reported. Less frequently, pericardial effusion, cardiac tamponade, and cardiac failure may be seen (195,317,323). These complications generally occur in patients with widespread myocardial involvement (311,324). Corticosteroids are the mainstay of the treatment for cardiac sarcoidosis but have not shown survival benefit in prospective trials (101,298). Other disease-modifying medications and immunosuppressants such as methotrexate, azathioprine, hydroxychloroquine, chloroquine, cyclophosphamide, cyclosporine A, thalidomide, pentoxifylline, and infliximab have been used with varying success (306,308,312,325–327). A combination of steroids and another immunosuppressant may be used to limit steroid side effects. In patients with disseminated myocardial involvement, the use of antiarrhythmic drugs and automated implantable cardiac defibrillator as bridge therapy while waiting for cardiac transplant has been advocated to prevent sudden death (312).

NORMAL ANATOMY AND PHYSIOLOGY

The pericardium is composed of two principal layers, the visceral pericardium and the parietal pericardium. The visceral pericardium, or epicardium, is a single serous layer covering the surface of the heart and proximal great vessels (Fig. 62.1). The parietal pericardium consists of three layers. The innermost layer is a serous layer, continuous with the serous visceral pericardium. The space between the visceral serous and parietal serous layers is the pericardial space, and it contains a small amount of serous fluid for lubrication (<20 to 30 mL in adults, less in children). The middle layer of the parietal pericardium is fibrous, while the outer layer is collagenous connective tissue. The pericardium gets its arterial blood supply from the descending aorta and internal mammary artery, and its innervation from the phrenic and vagus nerves. Within the thoracic cavity, it is bordered anteriorly by the sternum, inferiorly by the diaphragm and a portion of the inferior vena cava, and posteriorly by the esophagus, aorta, pulmonary veins, and thoracic vertebrae (1,2).

The pericardium provides mechanical protection to the heart from the spread of neoplastic, infectious, and inflammatory diseases from adjacent structures. The presence of a small amount of fluid in the pericardial space allows for free movement of the heart throughout the cardiac cycle. The pericardium limits acute distension of the heart and therefore limits end-diastolic volume. It permits diastolic coupling of the two ventricles, whereby filling pressure abnormalities of one ventricle affect the other. Slow progressive accumulation of fluid within the pericardium is tolerated by stretching and growth of the parietal pericardium; however, rapid accumulation of even a small amount of fluid is tolerated poorly (3).

ACUTE PERICARDITIS

Symptoms

Acute pericarditis may present with precordial or substernal chest pain. The pain is described as squeezing, sharp, or dull and characteristically is worse in the supine position. The patient will prefer to sit upright leaning forward and may refuse to lie down to be examined. The pain worsens with inspiration, coughing, and with movement (4,5). Younger children may present with atypical symptoms. Respiratory distress is uncommon unless tamponade or pulmonary disease is present. Rarely, abdominal pain can result from hepatic distension in patients with quickly accumulating effusions. Fever may be present.

Physical Examination

The pathognomonic physical finding in patients with acute pericarditis is a friction rub. This is a high-frequency, scratching or

sandpaper-like sound caused by friction between the inflamed pericardial surfaces. The rub can be heard throughout the cardiac cycle. However, it may be intermittent. It often is heard best at the left sternal border or the apex. The rub is loudest when the heart is closest to the chest wall, such as when the patient leans forward, kneels, and/or inspires (6,7). Absence of a friction rub does not exclude pericarditis, particularly in patients with large effusions. In patients with large effusions or tamponade, the heart sounds may be muffled.

Cardiac Tamponade

Cardiac tamponade occurs when the heart is compressed by a fluid-filled pericardium. This causes restriction of ventricular and atrial filling and decreased cardiac output (8). Tamponade results from a sudden increase in pericardial fluid volume or from progressive increase in volume beyond the point of potential pericardial distension. On examination, tamponade is characterized by Beck's triad, which includes (a) distant heart sounds, (b) hypotension, and (c) elevated central venous pressure with jugular venous distension (9). Patients will have tachycardia, tachypnea, and a narrow pulse pressure with pulsus paradoxus. During the initial stages of tamponade, cardiac output is preserved by increased ejection fraction and heart rate. As these physiologic mechanisms are unable to maintain cardiac output, the patient will become unstable as systemic vascular resistance increases to maintain systemic blood pressure. This will cause the pulse pressure to narrow, with compromised systemic perfusion. Ultimately, decreased coronary perfusion pressure will result in decreased myocardial function, cardiac output, and blood pressure (8,9).

Pulsus paradoxus is defined as a decrease in systolic blood pressure of >10 mm Hg during inspiration. Normally during inspiration, systolic blood pressure decreases by 4 to 6 mm Hg due to decreased intrathoracic pressure and increased capacity of the pulmonary venous bed. With cardiac tamponade, the left ventricular (LV) diastolic volume is restricted by increased pericardial pressure, decreased pulmonary venous return, and shifting of the interventricular septum. Clinically, to determine the presence of pulsus paradoxus, the patient should be supine. A blood pressure cuff is inflated until the radial pulse is not palpable. With slow release of pressure, one should listen for the initial Korotkoff sounds. With inspiration, the Korotkoff sounds disappear, particularly in the presence of pulsus paradoxus. Cuff pressure should be slowly released until the Korotkoff sounds are heard throughout the respiratory cycle. The difference in pressure between the first Korotkoff sound and when it is heard with each heartbeat is the pulsus. If the pressure difference exceeds 10 mm Hg, pulsus paradoxus is present (10).

During inspiration in normal patients, intrathoracic pressure decreases with an increase in venous return to the right atrium. In patients with cardiac tamponade, however, expansion of

Figure 62.1. Heart specimen, showing the heart within the pericardial cavity (left) and the bilayered pericardium with the heart removed (right). (Courtesy of Dr. William D. Edwards, Division of Anatomic Pathology, Mayo Clinic, Rochester, MN.)

the right atrium is limited by pericardial pressure. Thus, during inspiration, there may be a paradoxical increase in central venous pressure. This is evident by Kussmaul's sign; a rise in observed jugular venous pressure during inspiration (3).

Chest Radiography

The absence of cardiomegaly by chest radiography does not exclude pericarditis or pericardial effusion. Tamponade can occur in patients with a normal-appearing cardiac silhouette. With progressively increasing effusion, the cardiac silhouette may assume a triangular or "water-bottle" shape, with normal pulmonary vascular markings (Fig. 62.2). Patients with chronic pericarditis may have calcification of the pericardium (Fig. 62.3). The remainder of the chest radiograph may suggest potential causes of the pericarditis, including tuberculosis, pneumonia, or neoplastic disease (4,5).

Electrocardiography

The electrocardiographic changes in patients with pericarditis are secondary to direct inflammation of the epi/myocardium or pressure exerted against the epicardium by pericardial fluid. Acute pericarditis is the most frequent cause of ST elevation in children. Low QRS voltages occur in all leads in the presence of large pericardial effusions or chronic pericarditis. Electrical

alternans, a cyclical variation of the QRS amplitude, may occur secondary to the pendular motion of the heart with a large pericardial effusion.

Four stages of electrocardiographic changes have been reported in patients with pericarditis (11). Stage 1 consists of ST-segment elevation in the lateral/inferior leads (I, II, aVF, aVL, V4-V6) (Fig. 62.4). Reciprocal ST-segment depression may be present in leads aVR and V1. PR interval depression can occur if atrial tissue is inflamed. In stage 2, the ST segment normalizes, and T-wave amplitude diminishes. In stage 3, the ST segment remains normal, but the T-waves become inverted in the lateral/inferior leads (aVF, aVL, V4-V6). Stage 4 is characterized by the relative normalization of the ECG, although some T-wave changes may persist (5,12).

Echocardiography

Echocardiography is the primary imaging methodology used for the diagnosis of pericardial effusions, which appear as an echo-free space around the heart (13). Fibrinous strands may be noted in the pericardial space (Fig. 62.5). Thrombus, adhesions, or metastases also may be noted. Echocardiography also is helpful in detecting other structural and myocardial causes of cardiomegaly (14).

With the patient in the supine position, a small effusion most commonly is seen posteriorly and may be detectable only in systole. A tiny space in systole that is not evident in diastole is normal. An effusion that is present during both systole and diastole is abnormal (15). As the volume of the effusion increases, fluid may be detected both anterior and posterior to the heart (Fig. 62.6). With large effusions, the heart may swing to and fro within the pericardial space. This swinging movement can be seen by M-mode echocardiography (Fig. 62.7). The earliest sign of hemodynamic impairment in cardiac tamponade is collapse of the right ventricular (RV) free wall in early to mid-diastole (Fig. 62.8) (16). The right atrial free wall may appear indented late in diastole (Fig. 62.9). Inferior vena cava dilation without normal inspiratory variation and abnormal ventricular septal motion also may occur. Thrombus may occur in the pericardial space and suggests a hemopericardium.

Normally, during inspiration, the intrapericardial and the intrathoracic pressures decrease equally. Thus, the left atrial and LV diastolic pressures and the pulmonary capillary wedge pressure decrease equally during inspiration. How-

Figure 62.2. A: Chest radiograph of a 2-year-old girl who presented with tachypnea. The patient required an emergent pericardiocentesis, after which (B) her cardiothymic silhouette had markedly decreased in size.

Figure 62.3. Chest radiograph of an adult with chronic pericarditis and resultant calcification of the pericardial space. (Courtesy of Dr. William D. Edwards, Division of Anatomic Pathology, Mayo Clinic, Rochester, MN.)

Figure 62.4. Electrocardiogram of a 17-year-old male 2 days after surgical repair of an atrial septal defect. Note the diffuse ST-segment changes including ST-segment elevation in the lateral and inferior leads.

Figure 62.5. Heart specimen, showing the heart within the pericardial space with a large effusion. Fibrinous stranding can be seen within the pericardial space. (Courtesy of Dr. William D. Edwards, Division of Anatomic Pathology, Mayo Clinic, Rochester, MN.)

Figure 62.6. Parasternal long-axis echo image showing a large pericardial effusion (asterisk). LV, left ventricle; RV, right ventricle; Ao, aorta.

ever in tamponade, during inspiration, the intrathoracic pressure declines to a greater degree than the intrapericardial pressure. Thus, the gradient between the pulmonary capillary wedge pressure and LV diastolic pressures decreases with inspiration. Therefore, in cardiac tamponade, there is an exaggerated decrease in the mitral inflow velocity (E velocity) and velocity-time integral by at least 30%, with a

relatively increased atrial component during inspiration (A velocity) (Fig. 62.10A). Conversely, there is an exaggerated increase in tricuspid inflow velocity (tricuspid E velocity) and the velocity-time integral by at least 70% during inspiration (17,18). The aortic and pulmonary outflow changes mirror those of their respective atrioventricular valves (Fig. 62.10B).

Figure 62.7. M-mode echo image showing a large pericardial effusion (*asterisk*) anterior and posterior to the heart. Note the swinging motion of the heart evident in the M-mode signal.

Figure 62.8. RV collapse in early diastole in a patient with tamponade. Note that in the left image in systole (A), the full four-chamber view is noted, while in the right image in diastole (B), the RV free wall is compressed.

Figure 62.9. Right atrial collapse (*arrow*) in late diastole in a patient with tamponade. (Courtesy of Dr. Malek El-Yaman, West Virginia University Children's Hospital, Morgantown, WV.)

Cardiac Catheterization

With large accumulations of pericardial fluid, diastolic pressures rise in all four chambers and ultimately equalize (19). RV and pulmonary artery pressures may be elevated. Pulsus paradoxus can be seen on femoral artery pressure tracing (10). In patients with constrictive physiology, due to the equalization of the LV and RV end-diastolic pressures, the characteristic “square root” sign may be present on the LV pressure tracing (Fig. 62.11).

Other Imaging Modalities

Magnetic resonance imaging (MRI) or computed tomography (CT) can be useful if constrictive pericarditis is suspected. Active pericardial inflammation (a treatable cause of constriction) and hemodynamic evidence of constriction may be apparent using MRI. MRI is helpful in characterizing pericardial masses and congenital anomalies of the pericardium, such as absence of the pericardium and pericardial cysts (20).

Figure 62.10. Doppler echocardiographic patterns seen in an adolescent patient with a large pericardial effusion and tamponade physiology, including (A) mitral inflow pulse-wave Doppler and (B) abdominal aorta pulse-wave Doppler signals. Note the marked respiratory variation (respirometer below Doppler tracing in each figure) in peak velocities of both LV filling and aortic antegrade flow.

Figure 62.11. Cardiac catheterization tracing of a patient with physiology consistent with constriction. Note the “square root sign” (asterisk) secondary to equalization of LVEDP and RVEDP. LV, left ventricle; RV, right ventricle; Ao, aorta.

Management of Tamponade

After diagnosing cardiac tamponade, one should administer IV fluid immediately to increase diastolic filling pressure temporarily in order to stabilize the patient (21). Medications that decrease systemic arterial blood pressure such as vasodilators and diuretics should be avoided. Indications for pericardiocentesis include low cardiac output, hypotension, pulsus paradoxus >10 mm Hg, suspected bacterial pericarditis, pericardial effusions in immunocompromised hosts, or for diagnostic purposes when the etiology is unclear (22,23).

Pericardiocentesis should be performed in a monitored setting. The patient should be placed in a 30-degree head-up position and adequately sedated. Echocardiographic guidance allows for accuracy in entering the pericardial space usually from an apical approach, but is unnecessary in emergent situations (23). One can perform an agitated saline injection to confirm the location of the needle in the pericardial space. In the majority of patients, a drainage catheter should be placed for at least 48 hours to detect and drain recurrent effusions (22). Potential complications of pericardiocentesis include hemopericardium, pneumothorax, arrhythmias, myocardial puncture, coronary artery, aorta or internal mammary artery injury, and death (23,24).

Pericardial fluid should be analyzed for cell content, glucose concentration, protein concentrations, Gram stain, acid-fast bacilli stain, cultures (bacterial, viral, and fungal), and microscopic analysis (25). Specific bacterial or viral-specific antigens may be assessed using polymerase chain reaction (PCR) studies and latex agglutination studies. High triglyceride levels are diagnostic of chylopericardium. Adenosine deaminase activity levels can be measured to assist in the diagnosis of tuberculous pericarditis (26).

If the effusion is purulent, it may be too thick to adequately drain or it is loculated within the pericardium. In this case, surgical drainage will be necessary, and a subtotal pericardiectomy or pericardial window should be performed (27–29).

ETIOLOGY

Viral Pericarditis

The most common etiology of pericarditis in the pediatric population is viral. The most common viral causes of pericarditis are listed in Table 62.1. Coxsackievirus is the most common

TABLE 62.1 Pericarditis—Potential Viral Causes

Enterovirus (primarily Coxsackie B)	Measles
Adenovirus	Cytomegalovirus (CMV)
Influenza virus (A and B)	Respiratory syncytial virus (RSV)
Rubella	Herpes simplex
Mumps	Hepatitis B
Epstein-Barr virus (EBV)	HIV

viral cause of pericarditis in children (30). Patients often present 10 to 14 days after an upper respiratory or gastrointestinal infection, with precordial chest pain, fever, and a friction rub. Some patients present with abdominal pain. Patients with viral pericarditis generally are less toxic appearing than those patients with bacterial pericarditis. However, patients with viral pericarditis may appear toxic when there is associated myocarditis. Tamponade is rare in patients with viral myocarditis; however, patients should be monitored closely after initial diagnosis.

If collected, pericardial fluid usually is serous or serosanguineous, and displays lymphocyte predominance, although neutrophils may be common in the early stages of the illness. Viral cultures can be obtained from pericardial fluid, the nasopharynx, or the stool. PCR studies often are useful in determining a specific viral cause (31,32).

Specific treatment for viral pericarditis is symptomatic, including bedrest and oral nonsteroidal anti-inflammatory drugs (NSAIDs). If NSAIDs are unsuccessful, steroids may be considered once bacterial causes have been excluded. The use of colchicine with aspirin as first-line combination therapy decreases the likelihood of recurrence in adults. However, colchicine has not been well studied in the pediatric population (33). Resolution occurs in days to weeks, with complete resolution usually in <6 weeks. Relapse occurs in a small subset of patients, typically improving with reinstitution of NSAIDs or steroids. Constrictive pericarditis rarely occurs as a late complication of viral pericarditis.

Bacterial Pericarditis

Bacterial pericarditis is a serious, life-threatening disease. It presents most frequently in patients under 2 years of age (34). Patients present with symptoms of fever, chest pain, friction rub, and muffled heart sounds, but may be in shock on presentation. In addition, patients have dyspnea, tachypnea, and tachycardia out of proportion to the fever. Bacterial pericarditis can result from hematogenous dissemination or direct contact. The lung is the most common origin of dissemination, particularly when the agent is *Staphylococcus aureus*, *Haemophilus influenzae*, and *Streptococcus pneumoniae*. Septic arthritis, osteomyelitis, meningitis, or soft tissue infection also may be the source for hematogenous dissemination (34–37).

In bacterial pericarditis, the pericardial fluid demonstrates a marked predominance of neutrophils, and cultures typically are positive for the causative organism. Latex agglutination studies of the pericardial fluid, serum, or urine may be helpful if antibiotics have been given prior to obtaining a sample of pericardial fluid. Potential bacterial causes of pericarditis are listed in Table 62.2. *Staphylococcus aureus* is the most common bacterium isolated, accounting for half of the cases of bacterial pericarditis (34). Also, it is the most common cause of postoperative bacterial pericarditis (i.e., occurring within

<i>Francisella tularensis</i>	<i>Anaerobes</i>

3 months of a cardiac operation) (38). Anaerobic bacteria should be considered in patients with concurrent lung abscess, abdominal infection, or a history of blunt chest trauma.

Importantly, antibiotics alone are not sufficient to treat bacterial pericarditis. All patients require percutaneous or surgical drainage of the pericardial cavity. If the purulent pericardial fluid cannot be aspirated percutaneously, a surgically created window or pericardiectomy will be required (29). Streptokinase administered in the pericardium may improve drainage (39,40). Broad-spectrum antibiotics are mandatory and initially should be directed toward the most common organisms (*Staphylococcus aureus* and *Haemophilus influenzae*). Initial treatment should include an intravenous penicillinase-resistant penicillin (nafcillin or oxacillin) or vancomycin in patients at risk for methicillin-resistant *Staphylococcus aureus*, as well as a third-generation cephalosporin (ceftriaxone, cefotaxime) (34,38,41). An aminoglycoside may be added for immunocompromised patients. Specific therapy can be tailored once specific culture/sensitivity results are known. Patients with bacterial pericarditis should be treated for at least 3 to 4 weeks with intravenous antibiotics.

Survival for patients with bacterial pericarditis currently is >90% (39,41). Risk factors for poor outcome include young age at diagnosis, septicemia, tamponade, delay in diagnosis, inadequate drainage, concurrent myocarditis, and a staphylococcal etiology (37,39,42). Constrictive pericarditis can be a late complication (36,39), most commonly associated with *Staphylococcus aureus*, *Haemophilus influenzae*, or *Streptococcus pneumoniae* infections.

Tuberculous Pericarditis

Once common throughout the world, *Mycobacterium tuberculosis* pericarditis now occurs most frequently only in developing nations. The typical onset is insidious with symptoms of low-grade fever, night sweats, weight loss, malaise, dyspnea, and chest pain. The presentation may be complicated by subacute pericardial tamponade. Tuberculous pericarditis often occurs due to direct extension of miliary tuberculosis or lymphatic spread into the pericardium. Hematogenous spread may occur without evidence of pulmonary infiltrates. Most patients have a positive Mantoux skin test.

The pericardial fluid, when aspirated, is serosanguineous or hemorrhagic with lymphocyte predominance. Acid-fast bacilli

may be seen on auramine-rhodamine fluorescent-stained smears (43). Pericardial biopsy is useful to provide histologic confirmation. Pericardial fluid adenosine deaminase levels are diagnostic for tuberculous pericarditis if >50 U/L (26,43,44). Mycobacterium cultures may take up to 6 weeks to grow; thus, treatment should be initiated before confirmation of diagnosis.

Multidrug therapy is essential due to the risk of drug-resistant tuberculosis. A treatment regime of rifampicin, isoniazid, pyrazinamide, and ethambutol for at least 2 months, followed by isoniazid and rifampicin for another 4 months is highly effective (43). One or two months of steroid therapy may be useful to reduce inflammation and increase pericardial fluid resorption (45). Early in the course of the disease, pericardiectomy is difficult due to the presence of diffuse inflammatory and caseous material. Some investigators recommend delaying pericardiectomy for at least 6 weeks, although this remains controversial (43,46). Tuberculosis is a common cause of chronic pericardial effusion, and constrictive pericarditis may develop after recovery. Worldwide, tuberculous pericarditis is one of the leading causes of constrictive pericarditis (43).

HIV and Other Infections

Pericardial effusions are common in patients with human immunodeficiency virus (HIV) and are present in up to 25% of children with HIV infection (47–49). Children with HIV rarely develop tamponade. Pericardial fluid cultures typically are negative. Immunocompromised patients, including patients with HIV, are at risk for rarer causes of pericarditis, including parasitic and fungal causes (Table 62.3). In developing nations, concurrent infection with tuberculosis and HIV is common. The presence of HIV is a significant risk factor for developing tuberculous pericarditis (43).

Other Causes of Pericarditis and Pericardial Effusion

Renal Failure

Pericarditis occurs in 10% of patients with chronic renal failure (50,51). It is more common in patients with concurrent systemic lupus erythematosus (SLE), or drug-induced in those receiving hydralazine for hypertension. Most pericardial effusions will resolve with efficient dialysis (51). The pericardial fluid typically is serous. Care should be taken with heparinization in these patients, as a pericardial hemorrhage can occur with resultant tamponade. NSAIDs can be given for chest pain, but do not affect the size of the effusion. Pericardiocentesis should be performed for the usual indications, including patients suspected of having bacterial pericarditis and in those with hemodynamic compromise. If the effusion fails to resolve with dialysis, or if constriction develops, pericardiectomy may be necessary (51).

Hydralazine	

Kawasaki Disease

During the acute phase of Kawasaki disease, one-third of patients have a pericardial effusion, which typically resolves within 2 weeks. Effusions related to this inflammatory process do not commonly progress to tamponade, but this has been reported (52,53).

Drug-Induced Pericarditis

Drug-induced pericarditis may occur in patients treated with the medications listed in Table 62.4. The most common offenders are hydralazine, isoniazid, procainamide, and phenytoin. Antinuclear antibodies often are elevated in these patients. Effusions due to a lupus-like effect rarely progress to tamponade (54). Treatment includes discontinuing the offending drugs and initiation of NSAIDs. Patients with hypersensitivity reactions to penicillin and cromolyn sodium in association with pericardial effusion have been reported (55,56).

Hypothyroidism

The hypothyroid patient with a pericardial effusion most commonly is asymptomatic. It occurs in up to 80% of patients with myxedema, but is rare in patients with only mild hypothyroidism (57). Cardiac tamponade is exceedingly uncommon due to the slow accumulation of fluid (57). Patients present with paradoxical bradycardia, unlike others with pericardial effusions who usually have tachycardia. If pericardiocentesis is required, the fluid contains elevated protein and mucopolysaccharides (58). Most effusions will resolve gradually after initiation of thyroid hormone replacement therapy.

Chylopericardium

Chylous pericardial effusion may occur in patients following congenital heart surgery, particularly after trauma to the thoracic duct or in patients with elevated central venous pressures (59,60). Concurrent chylous pleural effusion may be present. Chylopericardium can occur in patients with mediastinal masses that obstruct lymphatic drainage, and in association with cystic hygromas, radiation therapy, or pancreatitis. It rarely may be idiopathic. The pericardial fluid obtained is milky-colored, with elevated triglyceride and protein levels. Patients should be given a low-fat or median-chain triglyceride diet, initiated after a period of parenteral nutrition without oral intake to allow resolution of the chylous effusion. Persistent chylous effusions can be treated by thoracic duct ligation. Some patients may require palliation with a pericardial window, pericardiectomy, or placement of a pericardioperitoneal or pleuroperitoneal shunt (59,60). Successful use of intravenous octreotide has been reported in some patients with chronic chylous pleural effusions (61).

Trauma

Blunt and penetrating cardiac trauma may result in hemorrhagic pericardial effusion. In cases of trauma, the usual Beck's triad of symptoms (distant heart sounds, hypotension, and jugular venous distension) rarely occurs, and echocardiography is diagnostic (9). All symptomatic patients require emergency pericardiocentesis. Iatrogenic hemopericardium also can occur during placement of central venous lines and invasive cardiac procedures. A pneumopericardium may be present in patients after an esophageal rupture (Fig. 62.12).

Neoplastic Disease

Primary tumors of the pericardium are rare. Metastatic disease is more common. Primary neoplasms include lymphoma, malignant teratoma, mesothelioma, and angiosarcoma. Potentially metastatic tumors include Hodgkin disease, non-Hodgkin lymphoma, leukemia, malignant melanoma, Wilms tumor, neuroblastoma, Kaposi sarcoma, and bone/soft tissue sarcomas (62–65). Nonmalignant congenital intrapericardial lesions may occur, including pericardial cysts, extralobar pulmonary sequestration, cystic lymphangioma, bronchogenic cysts, and pericardial teratomas (66–70). Teratomas can be large and cause hydrops fetalis in the fetus (71). Surgical excision of these large tumors, when possible, is curative (67).

Pericardial effusions often occur in patients with malignancies, independent of the primary tumor, due to infectious causes or metastatic invasion of pericardial lymphatics. Pericarditis can occur as a complication of certain chemotherapy agents, listed in Table 62.4. Diagnosis of the cause of a malignant effusion can be made using cytologic analysis and culture of pericardial fluid (72).

Patients who have received mediastinal irradiation are at increased risk of pericardial involvement after chemotherapy. Up to 5% of patients receiving mediastinal irradiation will develop pericarditis, typically from 2 months to 2 years after treatment (73). The patient may present with only mild symptoms or may progress to fulminant constrictive pericarditis.

Figure 62.12. Chest radiograph of an adolescent patient who presented with chest pain after an esophagogastroduodenoscopy procedure. Perforation of the esophagus had occurred, with resultant pneumopericardium evident. (Courtesy of Dr. Malek El-Yaman, West Virginia University Children's Hospital, Morgantown, WV.)

(74). Most cases improve with treatment with NSAIDs, but pericardiectomy may be necessary for recurrent effusions (75). Steroids are required in some patients (76).

Postpericardiotomy Syndrome

Postpericardiotomy syndrome usually occurs at least 1 week after intracardiac or pericardial surgery. Because there is pericardial and pleural inflammation, these patients frequently have pleuritic chest pain. It has been estimated to occur in up to 30% of patients following surgery (77,78). Postpericardiotomy syndrome typically occurs as a single episode, although it can recur weeks to years later. Children younger than 2 years old rarely are affected (79). Postpericardiotomy syndrome may produce irritability, malaise, decreased appetite, and arthralgias. Physical examination will reveal a friction rub and tachycardia. The patient may have signs of fluid retention. Cardiac tamponade is rare, but can occur (80).

The cause of postpericardiotomy syndrome remains speculative. The most likely etiology however is that of an autoimmune reaction (81,82). Postpericardiotomy syndrome can occur after blunt cardiac trauma, pacemaker lead placement, and in Dressler's syndrome (postmyocardial infarction syndrome) (83). While postpericardiotomy syndrome may occur after any cardiac operation, it is most frequent after repair of atrial septal defects, ventricular septal defects, and Tetralogy of Fallot (77). It occurs in up to 50% of pediatric patients after cardiac transplantation (84). Serum laboratory evaluation may reveal nonspecific inflammatory markers, including elevated erythrocyte sedimentation rate or C-reactive protein, and an elevated white blood cell count. Echocardiography may reveal an effusion, which typically reaches its maximal size by the 10th postoperative day (77).

Postpericardiotomy syndrome typically is benign and self-limited. Treatment includes diuretics for fluid retention and NSAIDs. Pericardiocentesis may be needed for symptomatic effusions (85). Aspirin is the primary anti-inflammatory medication recommended, in doses as high as 30 to 75 mg/kg/d in four divided doses for 4 to 6 weeks. As postpericardiotomy syndrome resolves, the drug is then tapered (85,86). In patients refractory to NSAIDs, or in those with large effusions, prednisone (2 mg/kg/d, maximum dose 60 mg daily, for 1 week with a 4-week taper) can be effective (87). Patients with recurrent effusions may require pericardiocentesis or pericardiectomy (88,89).

Autoimmune and Connective Tissue Diseases

Pericarditis and pericardial effusions occur in many autoimmune and connective tissue diseases, including SLE, juvenile rheumatoid arthritis, dermatomyositis, periarteritis nodosa, mixed connective tissue diseases, Wegener granulomatosis, Takayasu arteritis, and the spondyloarthropathies. It has been estimated that 25% of pediatric patients with SLE develop pericarditis (90). This usually is treated with oral NSAIDs, but

potentially could require pericardiocentesis if hemodynamic compromise develops (91). Pericarditis occurs in 10% of patients with juvenile rheumatoid arthritis at the time of diagnosis. This usually is treated effectively with oral NSAIDs. Short courses of steroids hasten resolution of symptoms (92). Patients with acute rheumatic fever rarely will develop pericarditis (50). Pericardial effusions in patients with acute rheumatic fever respond well to NSAIDs.

Recurrent and Chronic Pericarditis

Pericarditis *recurs* when the underlying disease relapses, or when an effusion reaccumulates after discontinuation of previously effective medical therapy (4,93). This occurs most frequently in patients with postpericardiotomy syndrome, juvenile rheumatoid arthritis, or SLE (94,95). Treatment strategies include reinstitution of NSAIDs, colchicine, or oral steroids. Patients have been treated successfully with immune modulators including azathioprine and cyclophosphamide (95). Pericardiectomy should be reserved for the patient with multiple recurrences.

Chronic pericarditis is defined as pericardial inflammation lasting >3 months. Similar treatments can be used for symptomatic patients, including NSAIDs, steroids, and percutaneous or surgical drainage of the effusion when necessary (94,96). Intravenous immunoglobulin has been reported to be effective in some patients with chronic pericarditis (97).

Congenital Abnormalities of the Pericardium

Absence of the Pericardium

Complete or partial absence of the pericardium is rare. Most cases are identified incidentally at autopsy or surgery. Most commonly, partial absence of the pericardium is left sided (98,99). Up to one-third of patients have an associated cardiac defect or pulmonary anomaly, including bicuspid aortic valve, atrial septal defect, patent ductus arteriosus, tetralogy of Fallot, pulmonary sequestration, or bronchogenic cyst (98). Although usually asymptomatic, patients can present with nonspecific symptoms such as dyspnea, light-headedness, and chest pain. Rarely, sudden death occurs due to herniation of the left atrium, left atrial appendage, or right atrium through the defect (99). Compression of a coronary artery and torsion of the great vessels also may occur.

The apical impulse may be shifted leftward. Chest radiography reveals a leftward shift of the cardiac silhouette. The diagnosis is not typically made by echocardiography, although unusual scanning windows, cardiac hypermobility, and abnormal ventricular motion may be present (100). The entire cardiac structure is shifted to the left; thus, the RV cavity may appear enlarged from the standard parasternal windows (15). CT and MRI are diagnostic (Fig. 62.13) (20). Surgical repair is indicated for patients with cardiac chamber herniation, or

Figure 62.13. Cardiac MRI sequences in an adolescent patient demonstrating partial absence of the pericardium. Note the marked displacement of the heart into the left hemithorax. While the herniation of the apical LV wall is more subtle in this four-chamber view in systole (A), it becomes more apparent in the LV outflow-tract view in late diastole (B). (Courtesy of Dr. Malek El-Yaman, West Virginia University Children's Hospital, Morgantown, WV.)

Figure 62.14. Chest radiography (A) and CT scans (B, C) of a patient with a coarctation of the aorta and incidentally discovered pericardial cyst (asterisk).

in patients with a small defect if future herniation is possible (99). This can be performed either by patch closure of the defect, or by enlargement of the defect to prevent incarceration of the herniated tissue. Patients with complete absence of the pericardium usually are asymptomatic and require no treatment (98).

Pericardial Cysts

Pericardial cysts are congenital anomalies resulting from failure of fetal lacunae to coalesce into the pericardial coelom (101). Patients usually are asymptomatic. The cysts often are discovered incidentally on chest x-ray (Fig. 62.14A). A cyst can become infected or cause bronchial compression, and the patient may have chest pain, dyspnea, or cough (102,103). Due to the benign nature of pericardial cysts, usually no treatment is required. Sometimes cysts present as previously unknown masses in the thoracic cavity, and infection or neoplasm must be excluded (104). Cysts may appear as echo-free spaces adjacent to the heart. CT or MRI, in conjunction with a normal history and clinical exam, can confirm the diagnosis of a pericardial cyst (Fig. 62.14B,C) (20).

CONSTRICTIVE PERICARDITIS

Constrictive pericarditis is characterized by a thickened and fibrotic pericardium that restricts ventricular filling (Fig. 62.15). While focal constriction has been reported, the constrictive process usually involves the entire pericardium. Constrictive pericarditis can develop as an idiopathic process, but most commonly represents the end stage of various forms of pericarditis (105,106). Worldwide, tuberculous pericarditis is the most common cause of constrictive pericarditis (43).

With constriction, diastolic expansion of the ventricles is limited causing hemodynamic compromise. Early diastolic filling will be normal, with limited mid and late diastolic filling. Ventricular systolic function generally is normal. Pulmonary wedge and central venous pressures are increased due to elevated ventricular filling pressures (107). Patients may have dyspnea, fatigue, exercise intolerance, or syncope. Hepatomegaly, splenomegaly, jugular venous distension, edema, or ascites may occur. Auscultation may reveal a diastolic filling sound corresponding to abrupt cessation of ventricular filling ("precordial knock") (105,108). Chest radiography may be normal or may display pericardial calcification in 25% of patients (Fig. 62.3) (15). The electrocardiogram often is non-specific, but may demonstrate low-voltage QRS complexes and ST-segment of T-wave abnormalities.

Echocardiography shows paradoxical septal motion with a septal "bounce." The "bounce" refers to the septum shifting leftward with increased RV filling during inspiration, and then shifting back rightward with expiration due to improved LV filling. The superior and inferior vena cavae may be dilated due to elevated ventricular diastolic and central venous pressures. Subcostal imaging may demonstrate "diaphragmatic tethering," where the diaphragm is pulled toward the heart with each ventricular contraction. Doppler echocardiography demonstrates marked respiratory variation of both left- and right-sided flows (Fig. 62.16) (109). With inspiration, there is an exaggerated decrease in the mitral inflow velocity (mitral E velocity) and an exaggerated increase in tricuspid inflow velocity (tricuspid E velocity) (109). Conversely, in expiration, there is an exaggerated increase in mitral inflow velocity and an exaggerated decrease in tricuspid inflow velocity.

CT and MRI may reveal pericardial thickening and/or calcification (20). Cardiac catheterization demonstrates equalization of LV and RV end-diastolic pressures, left and right mean atrial pressures, and the mean pulmonary capillary wedge pressure. The "square root sign" refers to the early diastolic pressure decrease followed by a plateau on LV and RV pressure tracings, and results from rapid early diastolic filling with abrupt cessation (Fig. 62.12). The definitive treatment for constrictive pericarditis is radical pericardiectomy (96,108).

Figure 62.15. Severe constrictive pericarditis. Note the markedly thickened pericardium in this ventricular short-axis slice. (Courtesy of Dr. William D. Edwards, Division of Anatomic Pathology, Mayo Clinic, Rochester, MN.)

Figure 62.16. Hemodynamic filling patterns in constriction. These diagrams illustrate a patient with constrictive pericarditis and the corresponding Doppler echocardiographic patterns with inspiration and expiration. Note the (A) respiratory variation in ventricular filling and the corresponding Doppler features of mitral and tricuspid valve inflow and pulmonary vein (PV) and hepatic vein (HV) flow. B: Typical mitral inflow and hepatic vein pulsed-wave Doppler recordings in constriction. Inspiration starts with the upward deflection of the respirometer tracing, while expiration starts with the downward deflection of the tracing. Note the decrease in mitral inflow E velocity with inspiration, and increase with the onset of expiration (*left frame*). In hepatic vein flow, there is a prominent diastolic flow reversal with expiration. (Adapted from Oh JK. *The Echo Manual*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006.)

Differentiating Between Constrictive Pericarditis and Restrictive Cardiomyopathy

Restrictive cardiomyopathy commonly is an infiltrative process and includes amyloidosis, hemochromatosis, endomyocardial fibrosis, and eosinophilic cardiomyopathy. It may be idiopathic (110,111). Restrictive cardiomyopathy is characterized by markedly abnormal diastolic function with preserved systolic function.

The differentiation between constrictive pericarditis and restrictive cardiomyopathy often is difficult (107,112–114). Echocardiographic measurements of diastolic function in children often are confounded by factors including preload, heart rate, age, and body size (115). Differentiating between constriction and restriction is critical, since the definitive treatments for these disorders are markedly disparate (pericardiectomy vs. cardiac transplant) (Table 62.5).

Cardiac catheterization can be useful in differentiating constriction from restriction (Fig. 62.17) (107). In constrictive pericarditis, there is an inspiratory increase in the area of the RV pressure curve compared with expiration. The area of the LV pressure curve decreases during inspiration as compared with expiration. Conversely, in restrictive cardiomyopathy, there is an inspiratory decrease in the area of the RV pressure curve as compared with expiration. The area of the LV pressure curve is unchanged during inspiration as compared with expiration. Talreja et al. (107) have described a catheterization-based calculation called the *systolic area index*, which is obtained by taking the ratio of the area under the RV pressure curve to the area under the LV pressure curve in inspiration versus expiration (calculated as $(RV_{insp}/LV_{insp})/(RV_{exp}/LV_{exp})$) (Fig. 62.17). A systolic area index value >1.1 was 97% sensitive and 100% specific for diagnosing constrictive pericarditis. This study only evaluated adult patients and requires validation in a pediatric cohort.

Echocardiographic differentiation between constriction and restriction includes the factors listed in Table 62.5 and those depicted graphically in Figure 62.18. The characteristic

TABLE 62.5

Distinguishing Constrictive Pericarditis and Restrictive Cardiomyopathy

Finding	Constriction	Restriction
History of Cardiac Surgery	Common	Uncommon
Echo: Septal “bounce”	Common	Typically absent
Echo: Atrial size	Normal/mildly enlarged	Significantly enlarged
Echo: Systolic function	Typically normal	Normal or mildly decreased
Echo: Wall thickness	Normal	Normal or increased
Echo: Doppler changes with inspiration/expiration	Significant and common	Rare
CT: Pericardial thickening	Common	Typically absent
Cath: RVSP	<50 mm Hg	>50 mm Hg
Cath: LVEDP – RVEDP	<4 mm Hg	>4 mm Hg
Cath: Wedge pressure – RA pressure	<4 mm Hg	>4 mm Hg
Cath: RVEDP/RVSP	>0.33	<0.3
Cath: Systolic area index	>1.1	<1.1

RVSP, right ventricular systolic pressure; RVEDP, right ventricular end-diastolic pressure; LVEDP, left ventricular end-diastolic pressure; RA, right atrium.

Figure 62.17. Catheterization tracings in constrictive physiology (A) and restrictive cardiomyopathy (B). Note that both patients have early rapid filling with elevation and equalization of the left ventricular (LV) and right ventricular (RV) pressures at end expiration. In constrictive pericarditis, there is an inspiratory increase in the area of the RV pressure curve (orange shaded area) compared with expiration. The area of the LV pressure curve (yellow shaded area) decreases during inspiration as compared with expiration. Conversely, in restrictive cardiomyopathy, there is an inspiratory decrease in the area of the RV pressure curve (orange shaded area) as compared with expiration. The area of the LV pressure curve (yellow shaded area) is unchanged during inspiration as compared with expiration. (Reprinted from Talreja DR, Nishimura RA, Oh JK, et al. Constrictive pericarditis in the modern era. *J Am Coll Cardiol* 2008;51:317, with permission from Elsevier).

septal “bounce” occurs more commonly in constriction, while severe atrial enlargement is more typically observed in restriction. Doppler velocities, including mitral inflow, hepatic venous flow, tricuspid inflow, and pulmonary venous inflow, are affected by respiration in constriction. There may be a relatively normal peak mitral valve E velocity during expiration in constriction or restriction. These mitral valve signals can be differentiated by the respiratory variation that occurs in constriction (increased E velocity during expiration), and the short deceleration time (DT) that occurs in restriction. Normally, hepatic vein Doppler waveforms will demonstrate larger systolic and diastolic forward flow waves compared to small systolic flow reversal and diastolic flow reversal waves. In constriction, decreased LV filling on inspiration allows for increased RV filling, causing hepatic vein diastolic forward flow to increase. In expiration, hepatic vein diastolic forward flow decreases, and significant flow reversals in diastole may occur. Thus, in patients with constriction, the flow may appear normal with inspiration, while marked diastolic reversals will be seen with expiration (Fig. 62.18). Conversely, in restriction, marked reversals in the hepatic veins occur with inspiration, and may occur in both systole and diastole. Mitral, tricuspid, and pulmonary vein velocities rarely are affected by respiration in patients with pure restriction. Importantly, the

Figure 62.18. Diagram of Doppler velocities from mitral inflow (MV), mitral annulus velocity, and hepatic vein (HV), and the ECG and respirometer recordings indicating inspiration (I) and expiration (E). Note the relatively similar peak mitral valve E velocity in normal, constriction, and restriction in expiration. The striking difference is the respiratory variation seen in constriction, with increased E velocity during expiration, and the short deceleration time (DT) seen in restriction. Patients with constriction will have normal or even increased tissue Doppler (TD) early diastolic mitral annulus (e') velocities, compared to patients with restriction, whose e' velocities are markedly blunted, typically below 8 cm/s. Examining hepatic vein flow, the normal patient will have larger systolic (S) and diastolic (D) flow waves compared to tiny insignificant systolic flow reversal (SR) and diastolic flow reversal (DR) waves. In patients with constriction, marked diastolic reversals will be seen with expiration (arrow), while the flow may appear normal with inspiration. Conversely, in restriction, marked reversals in the hepatic veins are typically seen with inspiration, and may occur in both systole and diastole (arrows). (Modified from Oh JK. *The Echo Manual*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006.)

diastolic flow reversals seen on expiration in constriction may not be evident in patients with tachycardia or atrial fibrillation. In these situations, augmented systolic reversals actually may be seen on expiration instead of prominent diastolic reversals.

Tissue Doppler imaging can be helpful in the differentiation of constriction and restriction (Fig. 62.18). In normal pediatric subjects beyond infancy, the early diastolic septal mitral annulus velocity (e') should be between 9 and 16 cm/s. In constriction, the e' velocity is normal or even increased as compared to normal. In restriction, the e' velocity often is <8 cm/s (similar to other cardiomyopathies) (15,116). In normal hearts, the lateral mitral annulus e' velocity is greater than the septal mitral annulus e' velocity. But, in constriction, the septal mitral annulus e' velocity can be greater than or equal to the lateral mitral annulus e' velocity, a paradoxical finding called *mitral annulus reversal* (117). This reversal of mitral annulus velocities is not seen in patients with restrictive cardiomyopathy.

Special Circumstances

Ventilator-Dependent Patient

During normal breathing, there is a decrease in intrathoracic pressure with inspiration and an increase with expiration. During positive pressure mechanical ventilation, the intrathoracic pressure changes are opposite those that occur with spontaneous breathing. Mechanical inflation of the lungs causes an

increase in intrathoracic pressure (118). As a result, the prominent Doppler respiratory variation in patients with constrictive pericarditis reverses during positive pressure ventilation, with mitral and pulmonary vein inflow velocities increasing during inspiration and decreasing in expiration (119).

Single-Ventricle Patient

The diagnosis of constriction in patients with single ventricle can be difficult. The traditional echocardiographic and catheter based methods rely on assessment of interventricular hemodynamics. With single ventricle patients, symptoms of dyspnea, fatigue, or exercise intolerance may be present, along with signs of venous congestion such as hepatomegaly, splenomegaly, jugular venous distension, and edema even in the absence of constriction. Evaluation of pericardial thickness by CT or MRI may provide the only specific findings for constriction. Constriction may cause protein-losing enteropathy after Fontan operation (120). It is important to consider constriction as a potential etiology in a patient after Fontan operation who presents with new-onset protein-losing enteropathy, since pericardiectomy could be curative (121).

Michael Gewitz ■ Kathryn A. Taubert

Infective endocarditis (IE) is a disease that is associated with considerable morbidity and mortality and remains a dreaded complication of structural heart disease. Although relatively rare in children, this cardiac infection with protean manifestations continues to have a disproportionate influence on clinical practice. Reported mortality rates are much lower now than in the preantibiotic era; however, overall morbidity and expense burden of prolonged and often intense medical and surgical therapies remain formidable.

Major advances in understanding this disease process have been made over the years. Additionally, the development and refinement of echocardiographic techniques have contributed to better diagnosis and management of endocarditis. Increasingly precise clinical criteria for the diagnosis of IE have been established (1,2) that assist physicians in making a better objective assessment of the varied clinical manifestations of this disease process.

DEFINITION

IE is a microbial infection of the endocardial (endothelial) surface of the heart. Native or prosthetic heart valves are the most frequently involved sites. Endocarditis also can involve septal defects, the mural endocardium, or intravascular foreign devices such as intracardiac patches, surgically constructed shunts, and intravenous catheters. Infective endarteritis is a similar clinical illness involving arteries, including the ductus arteriosus, the great vessels, aneurysms, or arteriovenous shunts.

At one time, endocarditis was classified as acute or subacute, but the recent tendency has been to avoid this terminology. It is preferable to describe the disease based on the etiologic agent involved. Low-virulence organisms such as α -hemolytic streptococci, enterococci, or coagulase-negative staphylococci usually cause a prolonged subacute form of the illness. On the other hand, *Staphylococcus aureus* and other pyogenic bacteria, such as *Streptococcus pneumoniae* or β -hemolytic streptococci, are usually associated with a more virulent or acute clinical illness.

EPIDEMIOLOGY

The epidemiology of heart disease in children has changed during the past several decades as has the epidemiology of IE itself. While it is difficult to get exact incidence data for IE because it is not a notifiable disease, the incidence is believed to have increased since the mid-1900s. The reported U.S. incidence from the early 1980s was approximately 1 in 1,280 (3). In a review of several published studies between 1986 and 1995, the estimated incidence in children overall was 0.3 per 100,000 children per year with a mortality of 11.6% (4).

The apparent increase in the incidence of IE in children reflects increased survival of patients with cardiovascular disease, paralleling advances in surgical and medical approaches to congenital heart disease (CHD) during the past several decades as well as to aggressive treatment regimens in neonatal and pediatric intensive care units. Whereas rheumatic heart disease was a major underlying cardiac condition in U.S. children with endocarditis until the 1970s, it has become an unusual underlying cardiac condition in more recent years. This is not true in developing countries, where endocarditis remains an important complicating factor in individuals with rheumatic heart disease.

CHD conditions, such as ventricular septal defect, patent ductus arteriosus, aortic valve abnormalities, and tetralogy of Fallot, are now the more common underlying conditions. An increasing proportion of children with IE have had previous corrective or palliative surgery for CHD, with or without implanted vascular grafts, patches, or prosthetic cardiac valves (5), and various reports have indicated that 50% to 70% of children with CHD have had previous cardiac surgery (3,6–9).

In neonatal IE, most cases occur in structurally normal hearts. Although relatively uncommon, increasing numbers of cases of neonatal IE have been reported since the 1970s. This reflects marked increases in cardiovascular interventions (surgical and nonsurgical) in newborns and young infants with concomitant increased use of prosthetic intravascular devices and insertion of long-term indwelling central venous catheters (5).

Patients with underlying cardiovascular disease may develop endocarditis at any age—in childhood, adolescence, or adulthood. In a pooled series of 723 children with congenital heart defects who developed endocarditis, the defects most frequently associated with IE were ventricular septal defect, tetralogy of Fallot, and aortic stenosis (6). Two recent, important reviews have characterized these epidemiologic changes succinctly. Yoshinaga et al. (10) identified increasing morbidity and mortality from IE in infants with CHD under 1 year of age. Rosenthal et al. (11) also found that it is younger children with CHD, especially those who have undergone surgical treatment, who constitute increasing number of IE patients as compared to earlier health care eras.

MICROORGANISMS

Most cases of endocarditis are caused by a relatively small number of microorganisms (Table 63.1). Experimental data and clinical observations indicate that some bacteria are more commonly associated with endocarditis than others. One of the most logical and intriguing explanations relates to bacterial adherence. Following careful *in vitro* studies, Gould et al. (12) found that bacteria most frequently responsible for endocarditis (e.g., viridans streptococci) display a propensity for

TABLE 63.1

Etiologic Agents of Infective Endocarditis in Infants and Children

Agent	Frequency
Streptococci	
α -Hemolytic	Most common
β -Hemolytic	Uncommon
Enterococci	Rare
Pneumococci	Rare
Others	Uncommon
Staphylococci	
<i>S. aureus</i>	Second most common
Coagulase negative	Uncommon, but increasing
Gram-negative agents	
Enterics	Rare
<i>Pseudomonas</i> species	Rare
HACEK ^a	Rare
<i>Neisseria</i> species	Rare
Fungi	
<i>Candida</i> species	Uncommon
Others	Rare

^a*Haemophilus, Actinobacillus, Cardiobacterium, Eikenella, Kingella.*

adherence to canine or human valves. In contrast, gram-negative organisms, seldom responsible for endocarditis, adhere rather poorly in this *in vitro* system.

Gram-positive cocci account for about 90% of recoverable bacteria in adult patients. Viridans group streptococci are responsible for most cases of endocarditis in all age groups in developing countries where, as a predisposing condition, rheumatic heart disease is prevalent. Staphylococci (*S. aureus* and coagulase-negative staphylococci) may account for more cases than do viridans group streptococci in developed countries where health care-associated infections are becoming more prevalent (13).

Similar trends have been noted in the pediatric age group (5,6,9,14). One study examined the prevalence of IE among children with *S. aureus* bacteremia. The prevalence of definite IE was approximately 12%, and definite or possible IE was 20%. Most of these children developed bacteremia from an infected intravascular device (15). Overall, enterococcal endocarditis occurs much less frequently in children than in adults.

Gram-negative organisms cause <10% of the endocarditis in children. However, neonates, immunocompromised patients, and injection drug users (IDUs) are at an increased risk for Gram-negative bacterial endocarditis. Among the fastidious Gram-negative bacilli of the HACEK group (*Haemophilus parainfluenzae*, *H. aphrophilus*, *H. paraphrophilus*, *H. influenzae*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingae*, and *K. denitrificans*), *Haemophilus* species are more common than the others in children, frequently affect previously damaged valves, and cause a subacute course of endocarditis. Rarely, *Neisseria gonorrhoeae* can cause endocarditis, presenting as an acute illness and affecting previously normal valves. Commonly, valvular destruction results from this organism.

In IDUs, other organisms isolated include *S. aureus* and occasionally *Candida* or other fungal species.

In instances of prosthetic valve endocarditis, the infective organisms differ depending on whether endocarditis occurs early (<2 to 3 months after surgical procedure) or late. Prosthetic valve endocarditis frequently is caused by *S. aureus* or coagulase-negative staphylococci. These infections often are implanted at the time of surgery and are seen ≤ 60 days after cardiac surgery, but coagulase-negative staphylococci may be present as late as 1 year after surgery.

Anaerobic organisms rarely cause endocarditis in children. Some individuals with the clinical picture of endocarditis, but with sterile routine blood cultures, may be infected with anaerobic organisms, which are not readily recovered by the usual culture methods in the clinical laboratory.

Fungal endocarditis is relatively unusual in children although it is one of the most feared forms of endocarditis. Complications, especially embolization, are frequent. *Candida* species are the most common organisms recovered; *Aspergillus* species, *Torulopsis glabrata*, and some other fungi (*Histoplasma*, *Coccidioides*, *Cryptococcus*) also have been reported. Fungal endocarditis is often noted in narcotic addicts or after cardiac surgery, but it also occurs in immunocompromised individuals and in neonates. In neonates, this infection may be a complication of intensive care measures, including hyperalimentation fluid infusion, use of broad-spectrum antibiotics for a prolonged time, and extended use of indwelling venous catheters. The mortality rate from fungal endocarditis is high, even with intensive medical and surgical therapy (5,14).

Approximately 5% to 10% of patients with endocarditis have negative blood cultures. A diagnosis of culture-negative endocarditis is made when a patient has clinical and/or echocardiographic evidence of IE but persistently negative blood cultures. The most common causes of culture-negative IE are current or recent antibiotic therapy or infection caused by a fastidious organism that grows poorly *in vitro* (5). Many of these individuals demonstrate subsequent proof of endocarditis, either in the operating room or at necropsy. Consultation with the clinical microbiologist is invaluable in looking for unusual and fastidious organisms. The clinician should carefully evaluate such cases for the possibility of other diseases. For example, IE can be confused with other causes of postoperative fever (e.g., postpericardiotomy syndrome) and may be appropriately included in the differential diagnoses of collagen vascular diseases or even certain oncologic diseases presenting in childhood.

PATHOGENESIS

Several independent factors and events are requisites for the development of IE. A pre-existing congenital or acquired lesion of the heart or great vessels is usually present, although in some instances, such as in IDUs and in patients with intravenous catheters, endocarditis may develop in the absence of cardiovascular structural abnormalities. The sequence of events resulting in endocarditis includes damage to the endothelium, formation of nonbacterial thrombotic endocarditis (NBTE) on the surface of the damaged endothelium, occurrence of a transient bacteremia, adherence of these bacteria to the NBTE, and subsequent proliferation of the bacteria within a vegetation.

Careful clinical and pathologic studies of endocarditis have defined the underlying structural cardiac or great vessel abnormalities that are the most frequent sites of infection. The risk of endocarditis varies for different underlying conditions (Table 63.2). A review of available reports by Steckelberg and Wilson (16) suggests that the incidence of endocarditis in the general population is approximately 5 cases per 100,000

TABLE 63.2 **Relative Risk of Endocarditis for Various Cardiovascular and Underlying Conditions**

High Risk

Prosthetic valves
Previous episode of endocarditis
Complex cyanotic CHD (e.g., single-ventricle states, transposition of the great arteries, tetralogy of Fallot)
Surgically constructed systemic artery-to-pulmonary artery shunts
Injection drug use
Indwelling central venous catheters

Moderate Risk

Uncorrected patent ductus arteriosus
Uncorrected ventricular septal defect
Uncorrected atrial septal defect (other than secundum)
Bicuspid aortic valve
Mitral valve prolapse with regurgitation
Rheumatic mitral or aortic valve disease
Other acquired valvar diseases
Hypertrophic cardiomyopathy

person-years. In high-risk groups, the incidence is substantially higher (300 to 2,160 cases per 100,000 person-years). The incidence in the moderate-risk groups ranges from 50 to 440 cases per 100,000 person-years.

Virtually all vegetations occur in areas where there is a pressure gradient with resulting turbulence of blood flow. Turbulent blood flow produced by certain types of congenital or acquired heart disease, such as flow from a high- to low-pressure chamber or across a narrowed orifice (e.g., where a jet through a small ventricular septal defect hits the right ventricular wall) traumatizes the endothelium. The sites of high-velocity jets where most IE vegetations occur are most often on the atrial side of the atrioventricular valves and the ventricular side of the semilunar valves. Intact cardiac endothelium is a poor stimulator of blood coagulation and is weakly receptive to bacterial attachment, whereas damaged or denuded endothelium is a potent inducer of thrombogenesis. Thrombogenesis at such a site results in the deposition of sterile clumps of platelets, fibrin, and occasionally red blood cells and the formation of NBTE. This provides an environment to which bacteria can adhere and eventually form an infected vegetation. NBTE also can be produced in children with indwelling intravenous catheters positioned in the right side of the heart. Such catheters may traumatize the endocardium or valvular endothelium, exposing the subendothelial collagen. Much has been learned about the pathogenesis of the developing site of infection by study in experimental animals of NBTE. Use of a polyethylene catheter in the rabbit model yielded important information. Very shortly after the vascular endothelium is injured by the catheter, platelets and fibrin will adhere to the site of injury. This meshwork continues to grow with further accumulation of platelets and fibrin; very few leukocytes are involved. Following the initial deposition of platelets and fibrin, thrombus formation occurs. Certain bacteria such as staphylococci and streptococci, commonly implicated in endocarditis, are potent

stimuli of platelet aggregation. In addition, the lysosomal granules of platelets may release hydrolytic enzymes or other active proteins that may potentiate the process.

Experimental studies have shown that circulating microorganisms are entrapped within this meshwork, becoming the nidus of infection. This usually occurs distal to the pressure gradient. The exception to this is valvular aortic stenosis, where the site of the vegetation is usually on the ventricular side of the aortic valve. A possible explanation for this finding is that in almost all instances of aortic stenosis there is at least some degree of aortic insufficiency. The ability of various microorganisms to adhere to specific sites determines the location of the infection. Mediators of bacterial adherence serve as virulence factors in the pathogenesis of IE. Numerous bacterial surface components present in streptococci, staphylococci, and enterococci have been shown in animal models of endocarditis to function as critical adhesions. Bacteria adhering to the vegetation stimulate further deposition of fibrin and platelets on their surface. Within this secluded focus, the buried microorganisms multiply rapidly.

The original site of infection subsequently changes in character. This change depends on several factors, including the microorganism involved. In endocarditis caused by α -hemolytic streptococci, the large colonies of bacteria become encased in an organizing mass of fibrin. The fibrin barrier has a direct effect on two important factors in the defense against infection: the prevention of the invasion by phagocytic leukocytes and the difficulty in penetration of the vegetation by antimicrobial agents. For reasons that are not fully appreciated, this type of vegetation formation does not frequently occur with some of the more virulent bacteria, such as *S. aureus*, where the infection rapidly destroys the valve or invades the myocardium with subsequent abscess formation.

There have been substantial gains within the past several years in the understanding of the pathogenesis of endocarditis largely because of the availability of newer molecular biologic techniques. These techniques have allowed the examination of individual virulence factors of Gram-positive cocci and the investigation of important host-cell interactions with microorganisms. Several specific surface structures of staphylococci, streptococci, and enterococci have been identified as markers of virulence (17). Mucosal surfaces are populated by endogenous bacteria. Transient bacteremia can be induced by trauma to a mucosal surface during various dental, oral, and surgical procedures; however, spontaneous bacteremia may also occur (16). The bacteremia associated with various tissue manipulations, including dental and surgical procedures, has been carefully studied. Spontaneous bacteremia also has been noted to occur after tooth brushing, chewing hard foods, or other daily events. Many dental procedures have been associated with bacteremia, particularly procedures known to induce gingival or mucosal bleeding. Transient bacteremia caused by viridans group streptococci and other oral microflora following tooth extraction may reach 80%. In experimental animals, large doses of bacteria are generally needed to induce endocarditis. In humans, it is likely that the dose in spontaneous bacteremia may be too small to lead to implantation of bacteria on cardiac lesions, but this concept is not evidence-based.

Following successful medical therapy, the cardiac lesions of endocarditis usually heal, although important residua can remain. Experimental studies in rabbits suggest that the resolution process includes endothelialization of the affected surface; phagocytosis of bacterial debris, sometimes with calcification; and subsequent organization by fibroblasts. Resulting hemodynamic abnormalities depend on the site of infection, the specific damage caused by the active vegetation, and the size and location of the abscess.

The immediate consequences of endocarditis, including vegetation formation, hemodynamic alterations, and the clinical syndrome, are only part of an evolving complex disease entity.

Distal manifestations of the disease in the past were considered to be the results of embolic phenomena. It is now recognized that additional mechanisms are involved in the pathogenesis of endocarditis that lead to peripheral manifestations. Many important extracardiac findings in endocarditis are related to immunologic mechanisms. Rheumatoid factor is present for 6 weeks or longer in sera of about half of the patients with endocarditis. This is considered to be due to a gradual hyperimmunization of the host. Rheumatoid factor is more frequently found in patients with endocarditis related to α -hemolytic streptococci or coagulase-negative staphylococci (low-virulence organisms) than in those caused by *S. aureus* (more virulent organisms). There is also correlation of the duration of infection with the presence of this antiglobulin. Rheumatoid factor tends to disappear from the sera with successful therapy. Immunologic mechanisms also underlie other clinical manifestations of the disease including the skin, subcutaneous tissues, and eye findings noted below (Clinical Features).

Another immunologic consequence of endocarditis is the development of circulating immune complexes in the sera of patients. This is due to extended exposure to foreign antigen, and these immune complexes disappear after successful antimicrobial therapy. Although deposition of immune complexes in renal parenchyma can occur, their precise role in pathogenesis has not been fully defined. The nephritis seen in patients with endocarditis may manifest itself microscopically as either focal or diffuse glomerulonephritis. In the focal lesion, there is often segmental fibrinoid necrosis of isolated lobules of the glomerular tuft. In the more diffuse form, there is marked cellular proliferation with interstitial round cell infiltrates. Immunofluorescence studies show granular deposits in the glomerular basement membrane and mesangium, usually associated with complement and immunoglobulin G (IgG) deposits, although IgA, IgM, and fibrinogen also have been demonstrated. Urinalysis results may be normal, but hematuria, cylindruria, and pyuria have been reported. Compromise of renal function may occur and appears to be more common in adults than in children. In addition to immune mechanisms, the kidney is an extracardiac site frequently affected in patients with endocarditis because of microscopic and macroscopic emboli of pathologic lesions. Many emboli are reportedly sterile. However, abscess formation also has been reported following septic embolization to the kidney. Abscess formation in other vital organs occurs as well (see below) and is involved in the pathogenesis of many of the life threatening sequelae of active IE.

CLINICAL FEATURES

Most clinical manifestations and complications of endocarditis are directly related to hemodynamic and structural changes caused by the local infection, to embolization from vegetations, or to immunologic reactions by the host. Bacteremia itself can also cause clinical findings such as fever and systemic toxicity. Endocarditis simulates a wide variety of disorders, including other infectious diseases, malignancies, and connective tissue diseases. It should be part of the differential diagnosis of any unusual or febrile illness in patients with underlying heart disease. If the diagnosis is not made promptly, the disease may escape detection until the process is far advanced with irreparable damage.

The clinical features differ, in part, depending on the primary infection site. Findings also may be different in children compared with adults. Most cases of endocarditis in adults are valvar, but endocarditis in children with congenital heart lesions may often involve other structures such as mural endocardium, patent ductus arteriosus, arteries or other vascular sites such as conduits or surgical shunts.

Endocarditis involving the left side of the heart frequently results in peripheral embolization, leading to ischemia, infarction, or mycotic aneurysms. In these cases, specific clinical findings depend on the localization of the emboli. In children, embolization from the right heart may be no less frequent, but such emboli, if small, are not as easily appreciated clinically because of filtration by the lungs. However, large pulmonary emboli may complicate endocarditis of the tricuspid valve.

Table 63.3 lists clinical findings and usual laboratory findings seen in patients with endocarditis. Fever is the most common finding in all patients with endocarditis, with the exception of neonates, and can vary depending on the infecting organism. When hemolytic streptococci are the causative agents, for example, fever is often low grade, reaching a maximum of 39°C. In contrast, endocarditis caused by *S. aureus* is frequently associated with high, spiking temperature elevations of $\geq 40^\circ\text{C}$.

Children with “subacute” endocarditis usually display slowly progressive nonspecific symptoms, including myalgias, arthralgias, headache, and general malaise. Fever may be relapsing and low grade. There is often a marked diminution in appetite. In contrast, with the acute form of endocarditis a toxic course is the rule with high fever, systemic debilitation, and more overt hemodynamic changes on presentation.

With diligent auscultation, new or changing murmurs are often heard. Since it may be difficult to recognize changes in a patient who has a pre-existing murmur, serial auscultation is essential. This will assist not only with diagnosis but also with management. For example, increased intensity of the diastolic murmur of aortic insufficiency should alert the examiner to the possibility of progressive aortic valvar deterioration,

TABLE 63.3

Clinical and Laboratory Findings in Patients with Endocarditis

Finding	Frequency ^a

which can lead to worsening left ventricular dysfunction, heart failure, and to the possible need for early valve replacement. Similarly, diminution of a continuous murmur in a cyanotic child with a prosthetic systemic-to-pulmonary shunt may be a sign of endocarditic involvement of the graft. Extracardiac findings can include splenomegaly, which may be seen in most instances when the disease has been present for weeks or months. Neurologic findings are present in about 20% of children with endocarditis and may simulate the picture of an abscess, an infarct, or aseptic meningitis. Renal abnormalities, including proteinuria, hematuria, and leukocyturia, can occur in the presence of emboli or in association with endocarditis-related immune complex deposition, as noted previously. The classically described signs such as small, tender, raised lesions on the pads of the fingers and toes (Osler nodes, Fig. 63.1A); small, nontender, flat erythematous lesions on the palms or soles (Janeway lesions, Fig. 63.1B); retinal hemorrhages with a central white spot (Roth spots, Fig. 63.1C); and splinter hemorrhages can also occur but are relatively rare in children.

Neonates represent a unique group in that many may have relatively few specific symptoms. In those newborns who are symptomatic, systemic hypotension, clinical signs compatible with generalized sepsis, or focal neurologic findings from central nervous system embolization may be clues to the development of endocarditis. Neonates appear particularly prone to

peripheral septic embolization and the development of satellite infections including meningitis and osteomyelitis.

LABORATORY DIAGNOSIS

The blood culture is the most valuable aid in making the diagnosis of endocarditis. Although a positive blood culture in a child with underlying or predisposing cardiac disease or a history of previous endocarditis does not necessarily indicate endocarditis, it is imperative that the diagnosis be considered in such a patient.

It is not possible to specify the exact number of cultures that should be obtained in each situation. The collection of three separate sets of blood cultures, each from a separate venipuncture over a 24-hour period, is adequate in most cases. In patients in whom the diagnosis of endocarditis is highly suspect, and the clinical situation is changing, arbitrary therapy should be considered after blood cultures have been obtained over an appropriate time period. In some situations, however, making careful observations and obtaining more blood cultures before initiating antibiotic therapy are appropriate.

Since the bacteremia in patients with IE is usually continuous, it is not necessary to obtain blood cultures only upon a

temperature elevation. The volume of blood to be collected is another consideration, particularly in instances where there is a likely low magnitude of bacteremia. Usually 20 to 30 mL of blood are collected from an adult patient, but this is not possible in a small child. Thus, 1 to 3 mL in infants and young children and 5 to 7 mL in older children are adequate, depending on the blood culture detection system (5). It is rare for IE to be caused by anaerobic bacteria; therefore, the emphasis is usually on inoculating blood into bottles designed for aerobic incubation. Usually, three blood cultures are obtained by separate venipunctures on the first day, and if there is no growth by the second day of incubation, two more may be obtained. It is usually not necessary to obtain more than five blood cultures over 2 days unless the patient received prior antibiotic therapy.

Other laboratory tests are not specific for confirming the diagnosis of endocarditis (Table 63.3), but they may be helpful in the management and follow-up of patients with this infection. Acute-phase reactants are commonly elevated. Initially, it is possible to find that the erythrocyte sedimentation rate (ESR) is only minimally elevated. As the disease progresses, the ESR will usually increase. It may remain elevated for some time even after documented bacteriologic cure. About half of the patients with endocarditis may have detectable rheumatoid factor or immune complexes in their sera. Anemia is common and may be hemolytic or may represent the anemia of chronic disease. It should be noted that chronic low-grade hemolysis also may be caused by a prosthetic valve in the absence of IE. Microscopic or macroscopic hematuria represents either renal embolization or immune complex related nephritis. Extreme leukocytosis is not a consistent finding and is more common in acute IE. In some situations, tests for the presence of antibodies to specific bacterial antigens are helpful. For example, antibodies against teichoic acid and against the cell wall peptidoglycan in severe staphylococcal infection may be present.

ECHOCARDIOGRAPHY

Two-dimensional echocardiography has become the principal diagnostic method in cases of suspected IE with sensitivities in children reported to be >80% (18). Neither sensitivity nor specificity of echocardiography is 100%. Therefore, a negative echocardiogram does not always rule out endocarditis. Transthoracic echocardiography (TTE) generally is more helpful in children with normal cardiac anatomy or with isolated valvar abnormalities and septal defects than it is in children with complex congenital anomalies (7). Echocardiographic examination is often definitive in patients destined for surgery.

Although data from adults indicate that transesophageal echocardiography (TEE) is superior to TTE for identification of vegetations (19), similar information in children is not available. Nevertheless, even in children, TEE adds to the ability to diagnose paravalvular leakage and complications such as dehiscence in prosthetic valve endocarditis as it does in older patients (20). Also, TEE is considered useful to assess the development of complications of left ventricular outflow tract IE and may be especially helpful in children who have had multiple surgeries for complex congenital cardiac disease or in others with limitations of TTE ultrasound windows such as children with chronic lung diseases or congenital chest wall deformities.

Echocardiography is particularly important as part of the serial evaluation of a patient with IE after the initial diagnosis. Select echocardiographic findings can indicate the likelihood of progressive complications including the need for operative intervention (Table 63.4) (21). Serial assessment of cardiovascular performance by echo can also be important to guide clinical decision making. Figure 63.2 demonstrates 2-D echocardiographic examples of both left and right heart IE.

TABLE

63.4

Echocardiographic Features Suggesting Potential Need for Surgical Intervention

Vegetation

Persistent vegetation after systemic embolization:

Anterior mitral leaflet vegetation, particularly with size >10 mm^a

One or more embolic events during first 2 wk of antimicrobial therapy^a

Two or more embolic events during or after antimicrobial therapy^a

Increase in vegetation size after 4 wk of antimicrobial therapy^{a,b}

Valvular dysfunction

Acute aortic or mitral insufficiency with signs of ventricular failure^b

Heart failure unresponsive to medical therapy^b

Valve perforation or rupture^b

Perivalvular extension

Valvular dehiscence, rupture, or fistula^b

New heart block^b

Large abscess, or extension of abscess despite appropriate antimicrobial therapy^b

^aSurgery may be required because of risk of embolization.

^bSurgery may be required because of heart failure or failure of medical therapy. From Bayer et al. Diagnosis and management of infective endocarditis and its complications. *Circulation* 1998;98:2936–2948, with permission.

DIAGNOSTIC CRITERIA

The diagnosis of IE can be straightforward in patients with classic manifestations including bacteremia (or fungemia), active valvulitis, peripheral emboli, and immunologic vascular phenomena. In many patients, however, classic peripheral manifestations may be few or absent, particularly in newborns, young infants, patients with acute-onset IE, and cases of right-sided endocarditis. Acute IE may evolve too quickly for immunologic vascular phenomena to develop, which are more characteristic of subacute IE.

Variability in the clinical presentation of IE requires diagnostic criteria that are both sensitive for disease detection and specific for its exclusion across all forms of the disease. A diagnostic strategy was developed (the Duke criteria) that uses a combination of clinical, microbiologic, pathologic, and echocardiographic findings (1). These criteria stratified patients with suspected IE into three categories: “definite” cases, identified either clinically or pathologically (IE proved at surgery or autopsy), “possible” cases (not meeting the criteria for definite IE), and “rejected” cases (those with no pathologic evidence of IE at autopsy or surgery; rapid resolution of the clinical syndrome with either no treatment or short-term antibiotic therapy; or a firm alternative diagnosis). In the mid-to-late 1990s, the criteria were validated in geographically and clinically diverse groups including children (22,23). Several refinements in the Duke criteria have been made recently to both the major and minor criteria (2). These so-called modified Duke criteria have been shown to be more sensitive in diagnosing IE in children than the original Duke criteria (24). The modified Duke criteria are shown in Table 63.5.

Figure 63.2. A: Mitral valve vegetations (arrows) in preteen patient with low-grade, persistent fever, weight loss, and malaise. Blood cultures grew α -hemolytic streptococci. Prior history of abnormal mitral valve known. IAS, intra-atrial septum; LV, left ventricle; RV, right ventricle. B: Right heart endocarditis involving vegetations on tricuspid valve (arrow) in a neonate. Blood cultures grew coagulase-negative staphylococci.

ANTIMICROBIAL THERAPY

General Principles

Complete eradication of the infecting microorganism in a vegetation usually requires several weeks of antibiotic therapy. Prolonged therapy is usually necessary for several reasons.

Within vegetations, organisms are embedded within the fibrin-platelet matrix and exist in very high concentrations. Additionally, there are relatively low rates of bacterial metabolism and cell division, which result in decreased susceptibility to beta-lactam and other cell wall-active antibiotics.

Bactericidal, rather than bacteriostatic, antibiotics should be chosen whenever possible to decrease the possibility of

TABLE 63.5A Definition of Infective Endocarditis According to the Modified Duke Criteria

Definite infective endocarditis (IE):

1. Pathologic criteria:

- A. Microorganisms demonstrated by culture or histologic examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen; or
- B. Pathologic lesions; vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis

2. Clinical criteria (see Table 63.5B):

- A. Two major criteria; or
- B. One major criterion and three minor criteria; or
- C. Five minor criteria

Possible IE:

- 1. **One major criterion and one minor criterion; or**
- 2. **Three minor criteria**

Rejected IE:

- 1. Firm alternative diagnosis explaining evidence of IE; or
- 2. Resolution of IE syndrome with antibiotic therapy for ≤ 4 d; or
- 3. No pathologic evidence of IE at surgery or autopsy, with antibiotic therapy for ≤ 4 d; or
- 4. Does not meet criteria for possible IE as above

From Li JS, Sexton DJ, Mick N, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis* 2000;30:633–638, with permission. Modifications shown in boldface.

TABLE 63.5B

Definition of Terms Used in the Modified Duke Criteria for the Diagnosis of Infective Endocarditis**Major Criteria**

1. Blood culture positive for IE
 - A. Typical microorganisms consistent with IE from two separate blood cultures:
 - i. Viridans streptococci, *Streptococcus bovis*, HACEK group, *S. aureus*; or
 - ii. Community-acquired enterococci in the absence of a primary focus; or
 - B. Microorganisms consistent with IE from persistently positive blood cultures defined as follows:
 - i. At least two positive cultures of blood samples drawn >12 h apart; or
 - ii. All of three or a majority of ≥four separate cultures of blood (with first and last sample drawn ≥1 h apart)
 - C. **Single positive blood culture for *Coxiella burnetii* or anti-phase-1 IgG antibody titer >1:800**
2. Evidence of endocardial involvement
 - A. Echocardiogram positive for IE (**TEE recommended for patients with prosthetic valves, rated at least “possible IE” by clinical criteria, or complicated IE [paravalvular abscess]; TTE as first test in other patients**) defined as follows:
 - i. Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation; or
 - ii. Abscess; or
 - iii. New partial dehiscence of prosthetic valve
 - B. New valvular regurgitation (worsening or changing or pre-existing murmur not sufficient)

Minor Criteria

1. Predisposition, predisposing heart condition, or injection drug use
2. Fever, temperature >38°C
3. Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions
4. Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor
5. Microbiologic evidence: positive blood culture, but does not meet a major criterion as noted above^a or serologic evidence of active infection with organism consistent with IE
6. **Echocardiographic minor criteria eliminated**

^aExcludes single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis.

HACEK, *Haemophilus parainfluenzae*, *H. aphrophilus*, *H. paraphrophilus*, *H. influenzae*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingae*, and *K. denitrificans*; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

From Li JS, Sexton DJ, Mick N, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis* 2000;30:633–638, with permission. Modifications shown in boldface.

treatment failures or relapses. Parenterally administered antibiotics are recommended because of the desirability of achieving high blood levels of the agents. In small children, intravenous antibiotics are preferred over intramuscular agents because of their small muscle mass. Use of heparin lock devices or indwelling catheters for intravenous therapy in older children and adults facilitates ambulation and activity. Outpatient (home) therapy can be considered in selected patients after initial treatment in the hospital and after confirming that these patients are hemodynamically stable and afebrile, have negative blood cultures, and are not at high risk for complications. Patient and parent compliance with the medical plan is important, and frequent monitoring by a home health provider is essential. There should also be easy access to a hospital for prompt reevaluation by an experienced physician should complications develop. When combinations of antibiotics are used, they can be tested in the laboratory for synergistic bactericidal activity, such as demonstrated by the combination of penicillin G with gentamicin against enterococci or α -hemolytic streptococci.

Documentation of cessation of bacteremia should be sought early in therapy as a means of measuring the adequacy of the

antibiotic regimen. Serum peak and trough antibiotic levels should be monitored when potentially toxic antibiotics (e.g., aminoglycosides) are used. This will ensure that levels are adequate and have not reached a toxic range. The clinician should still be alert to signs of toxicity even if serum levels remain within the generally accepted limits. All patients with endocarditis require close follow-up. Obtaining occasional blood cultures during the first 6 to 8 weeks after cessation of treatment is important because most relapses occur during this period.

The role of cardiovascular surgery in the therapy of endocarditis is determined by the site of infection and by the clinical course, especially the hemodynamic status of the patient. Decisions for surgical intervention must be individualized. Indications for surgery that are usually agreed upon include major or recurrent embolic events, persistent infection, and progressive cardiac failure (21,25), especially when the aortic or mitral valves are involved. Medical management alone of progressive valvar damage and resulting heart failure is dangerous. A decision to operate based on hemodynamic deterioration should not be delayed solely because the full course of antibiotic therapy has not been completed.

TABLE 63.6 Therapy of Native Valve Endocarditis Caused by Streptococci**Highly penicillin-susceptible viridans group streptococci and *streptococcus bovis* (MIC ≤ 0.12 $\mu\text{g/mL}$)**

Regimen	Dosage ^a	Route	Duration, weeks
Aqueous crystalline penicillin G sodium	200,000 U/kg per 24 h	IV in 4–6 equally divided doses	4
Or			
Ceftriaxone sodium	100 mg/kg per 24 h	IV/IM in 1 dose	4
Aqueous crystalline penicillin G sodium	200,000 U/kg per 24 h	IV in 4–6 equally divided doses	2 ^b
Or			
Ceftriaxone sodium	100 mg/kg per 24 h	IV/IM in 1 dose	2
Plus			
Gentamicin sulfate ^c	3 mg/kg per 24 h	IV/IM in 3 equally divided doses	2
Vancomycin hydrochloride ^d	40 mg/kg per 24 h	IV in 2–3 equally divided doses	4

Strains of viridans group streptococci and *S. bovis* relatively resistant to penicillin (MIC >0.12 to ≤ 0.5 $\mu\text{g/mL}$)

Regimen	Dosage ^a	Route	Duration, weeks
Aqueous crystalline penicillin G sodium	300,000 U/kg per 24 h	IV in 4–6 equally divided doses	4
Or			
Ceftriaxone sodium	100 mg/kg per 24 h	IV/IM in 1 dose	4
Plus			
Gentamicin sulfate ^c	3 mg/kg per 24 h	IV/IM in 3 equally divided doses	2
Vancomycin hydrochloride ^d	40 mg/kg 24 h	IV in 2 or 3 equally divided doses	4

Streptococci with MIC >0.5 $\mu\text{g/mL}$ as well as for enterococcal endocarditis caused by strains susceptible to penicillin, gentamicin, and vancomycin

Regimen	Dosage ^a	Route	Duration, weeks
Ampicillin sodium	300 mg/kg per 24 h	IV in 4–6 equally divided doses	4–6
Or			
Aqueous crystalline penicillin G sodium	300,000 U/kg per 24 h	IV in 4–6 equally divided doses	4–6
Plus			
Gentamicin sulfate ^c	3 mg/kg per 24 h	IV/IM in 3 equally divided doses	4–6
Vancomycin hydrochloride ^d	40 mg/kg per 24 h	IV in 2 or 3 equally divided doses	6
Plus			
Gentamicin sulfate ^c	3 mg/kg per 24 h	IV/IM in 3 equally divided doses	6

^aDosages recommended are for patients with normal renal and hepatic function. Maximum dosages per 24 h: penicillin, 18 million units; ceftriaxone, 2 g; gentamicin, 240 mg. Pediatric dose should not exceed that of a normal adult.

^bTwo-week regimen not intended for patients with known cardiac or extracardiac abscess, impaired renal function, symptoms of infection >3 mo in duration, impaired eighth cranial nerve function

^cDosage of gentamicin should be adjusted to achieve peak serum concentration of 3–4 $\mu\text{g/mL}$ and a trough concentration of <1 $\mu\text{g/mL}$ when 3 divided doses are used. Patients with a creatinine clearance of <50 mL/min should be treated in consultation with an infectious diseases specialist. Other potentially nephrotoxic drugs should be used with caution in patients receiving gentamicin therapy.

^dVancomycin therapy recommended only for patients unable to tolerate penicillin, ampicillin or ceftriaxone. Dosage should be adjusted to obtain peak (1 h after infusion completed) serum concentration of 30–45 $\mu\text{g/mL}$ and a trough concentration range of 10–15 $\mu\text{g/mL}$. Vancomycin dosages should be infused over at least a 1 h period to reduce risk of histamine-release “red man” syndrome.

MIC, minimal inhibitory concentration.

A detailed set of recommendations for antibiotic treatment of IE has been made by both the American Heart Association (AHA) (5,13) and the European Society of Cardiology (ESC) (26). Tables 63.6 and 63.7 are modified from these recommendations.

Streptococcal Endocarditis

Table 63.6 presents recommended treatment regimens for endocarditis caused by streptococci. Highly penicillin-susceptible streptococci have a minimal inhibitory concentration (MIC) to

TABLE 63.7 Therapy for Endocarditis Caused by Staphylococci in the Absence of Prosthetic Materials

Regimen	Dosage ^a	Route	Duration
Oxacillin-susceptible strains			
Nafcillin or oxacillin ^b	200 mg/kg per 24 h	IV in 4–6 equally divided doses	6 wk
With			
Optional addition of gentamicin sulfate ^c	3 mg/kg per 24 h	IV/IM in 3 equally divided doses	3–5 d
For penicillin-allergic (nonanaphylactoid type) patients:			
Cefazolin	100 mg/kg per 24 h	IV in 3 equally divided doses	6 wk
With			
Optional addition of gentamicin sulfate	3 mg/kg per 24 h	IV/IM in 3 equally divided doses	3–5 d
Oxacillin-resistant strains			
Vancomycin ^d	40 mg/kg per 24 h	IV in 2 or 3 equally divided doses	6 wk

^aDosages recommended are for patients with normal renal function. Pediatric dose should not exceed that of a normal adult.

^bPenicillin G 300,000 U/kg per 24 h IV in 4–6 equally divided doses may be used in place of nafcillin or oxacillin if strain is penicillin susceptible (minimum inhibitory concentration $\leq 0.1 \mu\text{g/mL}$) and does not produce β -lactamase.

^cGentamicin should be administered in close temporal proximity to vancomycin, nafcillin, or oxacillin dosing.

^dFor specific dosing adjustment and issues concerning vancomycin, see Table 65.6 footnotes.

penicillin ($<0.12 \mu\text{g/mL}$ [micrograms/mL]). They are the most common organisms causing endocarditis in children. The vast majority of these organisms is the viridans group (α -hemolytic streptococci); the rest are *S. bovis* (a nonenterococcal penicillin-susceptible group D *Streptococcus*) or β -hemolytic streptococci. For patients who are not penicillin allergic, intravenous aqueous crystalline penicillin G for 4 weeks is associated with high cure rates. This regimen is preferred for patients with impaired renal function or for those who are at risk of aminoglycoside toxicity. Ampicillin is an alternative to penicillin and has been used when penicillin is not available because of supply deficiencies. Ceftriaxone sodium given intravenously (IV) or intramuscularly (IM) daily for 4 weeks is also an acceptable regimen and is more commonly used today in the outpatient setting due to ease of dosing. Unacceptably high relapse rates occur when intravenous penicillin is used alone for 2 weeks.

A 2-week course of therapy with either penicillin or ceftriaxone combined with gentamicin has become increasingly popular and results in high cure rates in adults (13). This regimen is recommended for uncomplicated cases of native valve IE caused by highly penicillin-susceptible viridans group streptococci or *S. bovis* in patients at low risk for adverse events caused by gentamicin therapy. It should not be used for patients who have any of the following clinical features: endocarditis of >3 months' duration, prosthetic valve infection, shock or decreased perfusion, extracardiac foci of infection, mycotic aneurysm or cerebritis, renal failure, vestibular dysfunction, or presence of a vegetation visible by echocardiography. Reported relapse rates have been very low, and there are considerable savings associated with a shortened hospital stay. Experience with the 2-week regimen in children is limited, but it appears promising (with limited information).

Strains of viridans group streptococci and *S. bovis* with an MIC for penicillin of $>0.12 \mu\text{g/mL}$ and $\leq 0.5 \mu\text{g/mL}$ are referred to as relatively resistant strains. They are occasionally recovered from pediatric patients with endocarditis. These patients are best treated with 4 weeks of penicillin or ceftriaxone combined with 2 weeks of gentamicin.

Patients with IE caused by streptococci with an MIC $>0.5 \mu\text{g/mL}$ should be treated with ampicillin or aqueous crystalline

penicillin G plus gentamicin for 4 to 6 weeks. This regimen is also used for treating *Abiotrophia defectiva* and *Granulicatella* species (formerly known as nutritionally variant streptococci) and *Gemella* species. It is also used for enterococcal endocarditis susceptible to penicillin, gentamicin, and vancomycin. Enterococci uncommonly cause endocarditis in pediatric patients.

Patients allergic to penicillin (or ampicillin) frequently can be desensitized to enable treatment with these agents of choice. An effective alternative regimen when neither penicillin nor ceftriaxone can be used safely is intravenous vancomycin. For all streptococci with a penicillin MIC of $\leq 0.5 \mu\text{g/mL}$, 4 weeks of vancomycin therapy appears adequate. For more resistant streptococci (penicillin MIC of $>0.5 \mu\text{g/mL}$), treatment for 6 weeks of vancomycin (which may be combined with gentamicin) is recommended. Patients receiving these regimens should be closely monitored for renal toxicity and ototoxicity.

IE caused by *S. pneumoniae*, *S. pyogenes*, and group B, C, and G streptococci is relatively uncommon. There are few published reports of large series of cases evaluating therapeutic regimens for endocarditis caused by these microorganisms in patients of any age. Recent AHA recommendations review this aspect of the problem in more detail (13).

Staphylococcal Endocarditis

Table 65.7 presents recommended treatment regimens for endocarditis caused by staphylococci. Staphylococci are coagulase-positive (*S. aureus*) or coagulase-negative (*S. epidermidis* and various other species). Only a few *S. aureus* strains are penicillin susceptible because of production of enzymes called beta-lactamases. Therefore, antibiotic therapy must include a penicillinase-resistant penicillin (e.g., nafcillin or oxacillin) administered IV for 6 weeks. Addition of gentamicin for the first 3 to 5 days is optional. However, gentamicin's clinical benefit has not been formally demonstrated and it is associated with increased toxicity, so it should be used cautiously. Cefazolin may be used rather than nafcillin or oxacillin in patients with nonanaphylactoid-type penicillin allergy.

There are increasing rates of oxacillin resistance in hospital as well as community settings. Furthermore, recovery of

clinical *S. aureus* isolates highly resistant to vancomycin (27) has complicated the treatment of *S. aureus* endocarditis. The cyclic lipopeptide antibiotic daptomycin has been approved for *S. aureus* bacteremia and right-sided IE. Data on its use for endocarditis treatment in children are still somewhat limited. The reader is referred to guidelines from the Infectious Diseases Society of America for more information (28).

In nonaddicts, *S. aureus* endocarditis primarily involves the left side of the heart and is associated with mortality rates as high as 25% to 40%. *S. aureus* endocarditis in IDUs often involves the tricuspid valve. Cure rates for right-sided *S. aureus* endocarditis in IDUs are high (>85%) and may be achieved with relatively short courses of treatment (13).

Rifampin is effective against most staphylococci, but when it is used alone, resistance quickly develops. Routine use of rifampin is not recommended for treatment of native valve staphylococcal endocarditis.

Some coagulase-negative staphylococci and *S. aureus* strains are resistant to penicillin G and to penicillinase-resistant penicillins. Although in vitro evaluations may suggest that cephalosporins are effective, these organisms are indeed resistant to cephalosporins. They should not be used as therapeutic agents. Oxacillin-resistant staphylococci should be treated with vancomycin. In the penicillin-allergic individual who cannot be desensitized, intravenous vancomycin administered for 6 weeks is the drug of choice.

Gram-Negative Bacterial Endocarditis

Gram-negative bacteria that most often cause IE in children are the HACEK group of fastidious coccobacilli (*Haemophilus parainfluenzae*, *H. aphrophilus*, *H. paraphrophilus*, *H. influenzae*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingae*, and *K. denitrificans*). These microorganisms grow slowly in standard blood culture media, and recovery may require prolonged incubation. Typically, only a small portion of the blood culture bottles in patients with HACEK endocarditis demonstrate growth. In cases in which blood cultures are initially negative, the microbiology laboratory should be asked to retain blood cultures for at least 2 weeks in all patients suspected of having IE. Bacteremia caused by HACEK microorganisms in the absence of an obvious focus of infection is highly suggestive of endocarditis even in the absence of typical physical findings.

Infections with these organisms should be treated for 4 weeks with ceftriaxone or another appropriate third- or fourth-generation cephalosporin or ampicillin/sulbactam. In adults, ciprofloxacin is recommended in patients unable to tolerate cephalosporins or ampicillin. Fluoroquinolones are generally not recommended for patients younger than 18 years old, and an infectious disease consultation should be sought if this drug is considered.

IE caused by aerobic enteric organisms such as *Escherichia coli*, *Pseudomonas aeruginosa*, or *Serratia marcescens* is occasionally seen. Many such patients are IDUs, although occasionally a postoperative cardiac patient, an immunocompromised patient, or a neonate may develop endocarditis with one of these organisms. Therapy must be individualized and guided by in vitro antimicrobial susceptibility testing. Most experience has been with an extended-spectrum penicillin or a cephalosporin such as cefotaxime or ceftazidime together with an aminoglycoside such as gentamicin or amikacin. Therapy for at least 6 weeks is recommended. Cardiac surgery in combination with a prolonged course of antibiotic therapy is often necessary (13,29).

Gonococcal endocarditis, although rare and very aggressive, can be treated successfully with high-dose penicillin if the organism is penicillin susceptible. For penicillin-resistant organisms, an appropriate third-generation cephalosporin (such as cefotaxime or ceftriaxone) is recommended.

Fungal Endocarditis

Fungal endocarditis is a relatively new syndrome and is often a complication of medical and surgical advances. Its incidence in children is reported to have increased significantly in recent years (14). The prognosis is poor, with high mortality and morbidity. Fungal endocarditis can occur in immunocompromised patients (including preterm infants), IDUs, patients on broad-spectrum antibiotics for a prolonged period of time, and patients who have cardiovascular devices such as prosthetic cardiac valves or central venous catheters. About two-thirds of the cases of fungal endocarditis are due to *Candida* species (30). Despite aggressive combined medical and surgical interventions, mortality rates for fungal endocarditis remain unacceptably high. The survival rate for patients with mold-related endocarditis is <20%. Treatment of fungal endocarditis with antifungal agents alone is almost always unsuccessful, particularly in older patients. Amphotericin B is the most often recommended medical treatment option although the new echinocandin antifungal drug caspofungin is a viable alternative (30). Surgical replacement of the infected valve (native or prosthetic) and excision of infected tissue are usually required in conjunction with antifungal agents. Surgery is probably best performed after 1 to 2 weeks of medical therapy if the patient's hemodynamic status permits, but earlier if there is evidence of embolic phenomena. Antifungal therapy is then usually given for 6 weeks. Suppressive treatment with oral azoles is often maintained long term and sometimes for life. (For more detailed treatment options, the reader is referred to reference (30).)

Culture-Negative Endocarditis

Blood cultures can be negative in ≤20% of cases of endocarditis. This failure to culture the causative microorganism can be the result of inadequate microbiologic techniques, infection with highly fastidious bacteria or nonbacterial pathogens, or previous administration of antimicrobial agents before blood cultures were obtained (the latter of which is most common in the United States). Administration of antibiotics to patients before blood cultures are obtained reduces the recovery rate of bacteria by 35% to 40% (13). The antimicrobial susceptibility of the organism and the duration and nature of previous antimicrobial therapy together determine the length of time that blood cultures will remain negative. Patients with blood cultures that are initially negative after the patient has received only a few days of antibiotic therapy may still develop positive blood cultures after several subsequent days without antibiotics. The blood cultures of patients who receive longer courses of high-dose bactericidal antimicrobials may remain negative for weeks. Selection of the most appropriate medical therapy for patients with culture-negative endocarditis is difficult. The AHA and the ESC guidelines discuss various therapy recommendations for culture-negative IE (13,26).

Prosthetic Valve Endocarditis

Antibiotic therapy for patients with infected prosthetic heart valves must be appropriate for the specific infecting agent. Duration of therapy is usually 6 weeks or longer. Prosthetic valve infections owing to highly penicillin-susceptible streptococci (MIC ≤0.12 µg/mL) should be treated with 6 weeks of penicillin or ceftriaxone with or without gentamicin for the first 2 weeks. Infections caused by relatively or highly penicillin-resistant streptococci or enterococci should be treated as above except that gentamicin for 6 weeks should be combined with the penicillin or ceftriaxone. For penicillin-allergic patients who cannot be desensitized, vancomycin is recommended.

Staphylococcal endocarditis in the presence of a foreign body such as a prosthetic valve or graft should be treated with nafcillin or oxacillin (for an oxacillin-susceptible organism) plus both gentamicin and rifampin or vancomycin (for a methicillin-resistant organism). The aminoglycoside can be stopped after 2 weeks, but the other agents are continued for ≥ 6 weeks of therapy. In this situation, cardiac surgery is often required because of paravalvular abscess formation and difficulty eradicating the infection from the prosthetic material.

Therapy for other causes of prosthetic valve endocarditis is based on the results of in vitro MIC and minimal bactericidal concentration (MBC) tests and in vitro evaluation of antimicrobial synergy. Various regimens are discussed by the AHA (13).

Experience in adults with prosthetic valve endocarditis has emphasized that early surgical replacement of the infected valve may reduce the excessively high mortality rate associated with such infections. The timing of surgical removal and replacement of an infected prosthetic valve must be individualized. Some experts recommend that most or all patients with staphylococcal infection or prosthetic valve infection early after implantation should undergo valve replacement. Indications for operative intervention include significant valvular obstruction, progressive heart failure secondary to valvular insufficiency or dehiscence, fungal endocarditis, persistently positive blood cultures after appropriate antibiotics for 10 to 14 days, bacteriologic relapse after an appropriate course of therapy, and recurrent major emboli. Less definite indications for surgery include a single major embolus, echocardiographic demonstration of a large vegetation, and extension of infection to an annular abscess or a myocardial abscess.

Anticoagulation therapy during the treatment of IE remains controversial. A previous AHA statement (21) has noted the relative contraindication to anticoagulation during treatment of native valve IE in view of the confirmed risk for cerebral hemorrhage in these patients, particularly with left heart lesions. Conversely, most authorities agree that for prosthetic valve endocarditis, and for others with IE who already are on anticoagulation for other reasons, maintenance of anticoagulation is appropriate. This sentiment was confirmed as a preferred approach in a large survey of cardiologists and infectious disease specialists published in 2005 (31).

PREVENTION

Prophylaxis

Because of the high rates of morbidity and mortality associated with IE, any measure that can prevent the disease is desirable. Endocarditis can often be prevented by repairing the underlying cardiac defect or reducing the likelihood of bacteremia. In fact, the AHA has published recommendations for antibiotic regimens to be used before certain dental and surgical procedures for IE prevention since the mid-1950s (32). However, there has never been a prospective study in patients with underlying structural cardiac disease to determine definitively whether prophylactic antibiotics provide protection against development of IE during bacteremia-inducing procedures. Additionally, most instances of IE are not attributable to an antecedent invasive procedure but more likely result from routine activities of daily activities (chewing, toothbrushing, etc.). Within the past few years, some groups, including the AHA in 2007 (32), the UK's National Institute for Health and Clinical Excellence (NICE) in 2008 (33), and the ESC in 2009 (26), have reexamined the evidence underlying the antibiotic prophylaxis recommendations. These groups have significantly restricted the recommendations for who should receive routine prophylaxis (AHA and ESC) or have eliminated routine prophylaxis entirely (NICE). All three

organizations recognize that there are groups of individuals at increased risk of IE, including most with unrepaired congenital cardiac defects, acquired valvular heart disease with stenosis or regurgitation, a prosthetic cardiac valve or other prosthetic material, and/or a history of previous IE.

The AHA now limits prophylaxis recommendations to patients with "cardiac conditions associated with the highest risk of adverse outcome from IE" (Table 63.8), whereas the ESC limits its recommendations to "patients with the highest risk of IE." The patient groups are the same under either definition with the exception that the AHA includes cardiac transplant recipients who develop valvulopathy while the ESC does not include this group of patients in their recommendations.

For the above patient groups, both the AHA and ESC limit prophylaxis to dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa. They also list situations for which prophylaxis is not appropriate, such as routine anesthetic injections through noninfected tissue, taking dental radiographs, placement of removable prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, or shedding of deciduous teeth and bleeding from trauma to the lips or oral mucosa. None of the three groups recommend routine prophylaxis for most procedures involving the upper or lower respiratory tract, upper or lower gastrointestinal (GI) tract, or genitourinary (GU) tract. A question sometimes arises concerning tattooing or body piercing in patients who have CHD. While these procedures should be discouraged, and if undertaken they should be performed under sterile conditions, antibiotic prophylaxis for the prevention of endocarditis is not recommended.

The recommended prophylactic regimens are given in Table 63.9 and are those from the AHA (32). The antibiotic should be administered as a single dose 30 to 60 minutes before the procedure. Amoxicillin is the drug of choice for children who can take oral medications and who are not allergic to

TABLE 63.8

Cardiac Conditions Associated with the Highest Risk of Adverse Outcome from Endocarditis for Which Prophylaxis with Dental Procedures is Recommended

Prosthetic cardiac valve

Previous IE

Congenital heart disease (CHD)^a

Unrepaired cyanotic CHD, including palliative shunts and conduits

Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 mo after the procedure^b

Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)

Cardiac transplantation recipients who develop cardiac valvulopathy

^aExcept for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.

^bProphylaxis is recommended because endothelialization of prosthetic material occurs within 6 mo after the procedure.

TABLE 63.9 Prophylactic Regimens for Dental, Oral, or Respiratory Tract, Procedures

	Agent	Regimen (single dose 30–60 min before procedure)
Standard oral prophylaxis	Amoxicillin	50 mg/kg PO (maximum 2 g)
Unable to take oral medications	Ampicillin	50 mg/kg IM or IV (maximum 2 g)
	Or	
	Cefazolin or ceftriaxone	50 mg/kg IM or IV (maximum 1 g)
Penicillin allergic–oral regimen	Clindamycin	20 mg/kg PO (maximum 600 mg)
	Or	
	Cephalexin ^a	50 mg/kg PO (maximum 2 g)
	Or	
	Azithromycin or clarithromycin	15 mg/kg PO (maximum 500 mg)
Penicillin allergic and unable to take oral medication	Clindamycin	20 mg/kg IV (maximum 600 mg)
	Or	
	Cefazolin ^a	50 mg/kg IM or IV (maximum 1 g)

^aCephalosporins should not be used in individuals with immediate-type hypersensitivity reaction (urticaria, angioedema, or anaphylaxis) to penicillins.

penicillins. If a patient is already taking an antibiotic when he or she has a procedure that requires IE prophylaxis, an antibiotic from a different class should be chosen for prophylaxis rather than increasing the dose of the current antibiotic.

If any patient included by AHA or ESC in Table 63.8 (highest risk of adverse outcome/highest risk group) is undergoing a respiratory tract procedure to treat an established infection, the antibiotic regimen administered to them should contain an agent that covers organisms that cause IE. Similarly, if a patient is undergoing a GI or a GU tract procedure where there is an established infection, or for those who receive antimicrobial therapy to prevent wound infection or sepsis associated with a GI or GU procedure, the patient should receive a regimen that includes an agent effective against enterococci.

The risk of acquiring endocarditis may change after surgical or other reparative procedures. This risk could go down (e.g., successful closure of atrial septal defect or ventricular septal defect), not change (e.g., placement of palliative shunts/conduits), or could go up (e.g., replacement of a native cardiac valve with a prosthetic valve). Patients/parents should be reminded that a child's need for antibiotic prophylaxis could change as they evolve through various treatment programs.

Finally, the new AHA recommendations note that poor dental hygiene and periodontal or periapical dental infections may produce bacteremia themselves even in the absence of dental or oral procedures. The guidelines emphasize the importance of maintenance of good oral health as an important factor in preventing endocarditis in susceptible individuals. Clinicians are urged to educate their patients/parents in this regard and to frequently remind them of this need.

Ali N. Zaidi ■ Curt J. Daniels

Although chest pain is common in patients presenting to pediatric cardiology clinics, myocardial ischemia is rarely ever the etiology. The list of etiologies leading to myocardial ischemia is potentially long, and each diagnosis for the most part is uncommon. Myocardial ischemia must always be considered in any patient who presents with chest pain or has a known diagnosis that could lead to ischemia, that is, Kawasaki disease (KD). The consequences of not considering this diagnosis can be devastating. Unfortunately, many patients who suffer an ischemic episode do not present until after a myocardial event. This group of rare patients must undergo a rapid evaluation that leads to definitive therapy. The patient who presents with symptoms of chest pain before an event or in the middle of an event is the focus of this particular chapter. An algorithm based upon a detailed history, exam, and appropriate diagnostic testing should lead to the correct diagnosis and the ability to include or exclude myocardial ischemia from the differential diagnosis. For the purposes of this chapter, we do not review atherosclerotic coronary artery disease (CAD) as this is covered elsewhere (see Chapter 71).

DEFINITION

Myocardial ischemia is an imbalance between myocardial oxygen supply and demand. Left untreated, it results in angina pectoris, myocardial stunning, myocardial hibernation, or under the most severe instances, acute coronary syndromes such as myocardial infarctions.

From a supply standpoint, a reduction or decrease in coronary blood flow due to spasm or obstruction leads to low flow ischemia of the myocardium and eventually to an acute coronary syndrome or myocardial infarction. Also, coronary blood flow may be normal but myocardial oxygen supply reduced in cases of severe hypoxia. Cyanotic heart disease, severe anemia, and hemoglobinopathies all have the potential for significant hypoxia leading to myocardial ischemia.

On the demand side, an increase in myocardial oxygen demand, that is, exercise, may lead to ischemia if there is a limitation on a supply that under normal or steady-state conditions is adequate but is not sufficient during times of increased demand. Although this mechanism of ischemia may lead to an acute coronary syndrome, more commonly, patients suffer chronic chest pain during times of increased demand.

Therefore, in our pediatric population and adults with CHD, chest pain often stems from a benign etiology, but, rarely, it may portend imminent catastrophe. In this patient population, the diagnoses leading to ischemia must fall under these two broad categories to cause myocardial ischemia.

HISTORY

For the patient who presents with chest pain, a detailed history provides the most important information to include or exclude myocardial ischemia from the differential diagnosis. Myocardial ischemia causing chest pain has typical characteristics that, when present, requires further investigation. Chest pain is more likely ischemic in origin when it is associated with:

- Exertion more than at rest
- Dyspnea
- Diaphoresis
- Syncope

and is characterized as:

- Substernal pressure or burning rather than pain
- Pressure that radiates to neck or arm
- Fairly reproducible with similar activity
- Short lived; 2 to 10 minutes as opposed to hours

Other important historical features include how the pain is relieved. If a patient is able to continue to run and play and the pain goes away despite continuing activity, myocardial ischemia is less likely.

Excluding atherosclerotic CAD, where hypertension, diabetes, tobacco use, and hyperlipidemia are important risk factors, prior medical history tends not to be helpful in evaluating other causes except in KD. Patients diagnosed with KD should be extensively interviewed and old records obtained regarding history of treatment, echocardiogram results, and follow-up studies. Patients should also be screened for prior febrile illnesses that may have been mistaken for KD. A family history should screen for Marfan syndrome, other aortopathies, and hypertrophic cardiomyopathy. A prior surgical history where the coronary arteries were manipulated or reimplanted is important in a patient with typical ischemic chest pain. The surgical reports pertaining to the procedure and how the coronary arteries were either reimplanted or manipulated are important to the current care of the patient and future testing that would need to be done.

DIFFERENTIAL DIAGNOSIS

The etiologies for nonatherosclerotic CAD and myocardial ischemia remain rare and for the most part difficult to diagnose, require a high index of suspicion, and often involve advanced imaging studies. Most of the diagnoses are covered in other areas of this textbook and are detailed in those

chapters. This group of diagnoses can be divided into those involving the coronary arteries directly and those that involve the myocardium leading to myocardial ischemia.

Related to the Coronary Arteries

- Anomalous coronary arteries
 - Left main coronary artery from the pulmonary artery
 - Left main coronary artery from the right coronary cusp
 - Right coronary artery from the left coronary cusp
- Coronary artery fistula
- Coronary artery spasm
- Thromboembolic or embolic CAD
- Kawasaki disease
- Coronary artery dissection
- Ostial CAD s/p reimplantation
 - D-TGA arterial switch
 - Aortic root replacement
 - Ross procedure
- Intramyocardial bridging
- Atresia of the left coronary artery orifice

Related to the Myocardium (Supply/Demand Mismatch)

- Hypertrophic cardiomyopathy
- Severe aortic stenosis
- Dilated cardiomyopathy
- Tachycardia in the face of limited coronary blood flow

Other

- Severe hypoxia or cyanosis

EXAMINATION

The cardiovascular examination in a patient with concerns for myocardial ischemia may be completely normal. Important cardiovascular findings in specific disease states include

- Dynamic systolic ejection murmur consistent with hypertrophic obstructive cardiomyopathy. Nonobstructive patients may not have a left ventricular outflow tract murmur with dynamic maneuvers but carry the same risk for ischemia.

- Continuous murmur along the left or right lower sternal border consistent with a coronary fistula or anomalous left main coronary artery from the pulmonary artery (LCAPA).
- Patients with dilated cardiomyopathy and heart failure will have signs of elevated jugular venous pressure, third or fourth heart sound, holosystolic murmur of mitral regurgitation, peripheral edema, and hepatic enlargement.
- Harsh systolic ejection murmur of hemodynamically significant aortic stenosis.

ELECTROCARDIOGRAM

The electrocardiogram (ECG) remains the most important diagnostic test in the evaluation for myocardial ischemia. Many factors are involved in the interpretation of the ECG; age, autonomic tone, heart rate, race, gender, and body habitus. Standing, hyperventilating, and performing a Valsalva maneuver can all have an effect on ST segments with small degrees of ST depression or T wave inversions just from body position or maneuvers. Pellicia et al. (1) described abnormal ECGs in 40% of Olympic athletes who had structurally normal hearts.

When the ECG is being performed to evaluate myocardial ischemia, the ECG should be obtained during episodes of chest pain, when possible, or shortly thereafter. The presence of an old ECG or an ECG obtained when the patient did not have chest pain for comparison is crucial when trying to decide whether dynamic ST changes are present, therefore consistent with myocardial ischemia. The ECG findings depend on several major factors as follows:

- Duration of myocardial ischemia
- Presence of prior bundle branch block (BBB) or WPW (pre-excitation), paced rhythm that could alter the ECG findings of myocardial ischemia
- The extent of the myocardial ischemia—subendocardial, transmural
- Location of the myocardial ischemia; i.e., anterior, posterior

Duration, location, and extent of myocardial ischemia will determine the changes seen on ECG. Whether the ischemia is subendocardial or transmural will affect the ST changes and the interpretation of the ECG (Fig. 64.1). When acute transmural ischemia occurs, tall peaked T waves with ST elevation are produced from epicardial injury representing the ischemic zone at risk of myocardial injury. The location that represents

Figure 64.1. A: Represents subendocardial ischemia with the direction of injury toward the inner surface of the heart and therefore away from the surface chest leads. The injury current leads to ST depression. B: Represents transmural or epicardial injury with the injury current going toward the chest leads and therefore upright ST elevation. (Reprinted from Mirvis DM, Goldberger AL. *Electrocardiography*. In: Zipes DP, Libby P, Bonov TO, et al., eds. *Braunwald's Heart Disease*. 7th ed. Philadelphia, PA: Elsevier Saunders, 2005, with permission from Elsevier.)

Figure 64.2. Right bundle branch block (RBBB) with acute anterior myocardial infarction. There are Q waves in the right-sided precordial leads and ST elevation in leads V1-V6. (Reprinted from Mirvis DM and Goldberger AL. *Electrocardiography*. In: Zipes DP, Libby P, Bonov TO, et al., eds. *Braunwald's Heart Disease*. 7th ed. Philadelphia, PA: Elsevier Saunders, 2005, with permission from Elsevier.)

the ischemic zone is represented by the placement of the surface ECG:

- Inferior—leads II, III, aVF
- Anterior—V2-V6
- Anterior-septal—V1-V3
- Lateral—I, aVL
- Posterior—leads V1 and V2 with tall R waves and ST depression, usually accompanied by ischemic changes in the inferior leads.

With subendocardial ischemia, the ischemic zone is toward the inner ventricular layer (subendocardium) and the overlying precordial leads demonstrate ST depression. Subendocardial ischemia is the common pattern for patients experiencing chronic chest pain secondary to ischemia. Abnormal base-

line ECG with preexisting ST or T wave change, prior BBB or evidence of preexcitation can limit the typical findings of myocardial ischemia (Figs. 64.2 and 64.3) and make the interpretation of myocardial ischemia more difficult, if not impossible, without other diagnostic tools.

For pediatric and adolescent patients in particular, normal variants and other disease states may mimic ischemic ST changes and need to be differentiated from true ischemic ST changes. Repolarization changes, pericardial disease, digitalis effect, and electrolyte abnormalities may all be associated with ST changes (Figs. 64.4–64.7).

A completely negative ECG at the time of ongoing chest pain is extremely predictive of nonischemic chest pain. The risk of an acute myocardial event is <2% among patients with no prior history for CAD presenting with a negative ECG at the time of chest pain (2). Therefore, differentiating between ischemic and nonischemic ST changes is crucial in the evaluation of chest pain.

BIOMARKERS OF MYOCARDIAL INJURY

When myocardial injury occurs, enzymes from the myocardium are released approximately 2 hours later and can be detected by various assays. Cardiac troponin T and I and creatine kinase MB isoenzyme (CK-MB) are all important biomarkers of myocardial injury and, when elevated, signify myocardial damage with good sensitivity and specificity (3,4). After injury occurs, these enzymes will rise within 2 hours, and may continue to rise for several hours. By 12 hours, the CK-MB will begin to decrease and by 24 hours the sensitivity of the troponins remains high whereas the CK-MB sensitivity diminishes (5) (Fig. 64.8). The CK-MB false positives are possible due to trace amounts of CK-MB in skeletal muscle. Therefore, damage to skeletal muscle on a large scale may increase the amount of CK-MB in the blood stream. Additionally, cardiac enzymes may be elevated with perimyocarditis due to inflammatory changes to the myocardium.

Troponins I and T are more specific than CK-MB for myocardial injury. However, since the troponin assays are able to detect what is felt to be very small degrees of myocardial

Figure 64.3. LBBB with acute inferior myocardial infarction. There is ST elevation in the inferior leads II, III, aVF. The patient is in atrial fibrillation. (Reprinted from Mirvis DM, Goldberger AL. *Electrocardiography*. In: Zipes DP, Libby P, Bonov TO, et al., eds. *Braunwald's Heart Disease*. 7th ed. Philadelphia, PA: Elsevier Saunders, 2005, with permission from Elsevier.)

Figure 64.4. Normal variant repolarization abnormality. There is J-point elevation mostly seen in lead V4. There are no reciprocal ST depression and no PR depression to distinguish this from acute myocardial infarction and pericarditis, respectively. (Reprinted from Goldberger AL. *Myocardial Infarction: Electrocardiographic Differential Diagnosis*. 4th ed. St Louis, MO: Mosby-Year Book, 1991, with permission from Elsevier.)

damage, in all cases, this may not be due to CAD. Myocarditis, pericardial disease, and trauma may all yield a positive troponin result. Therefore, the context in which the assay is performed may be equally important to the interpretation of the result.

There is increased sensitivity and specificity of the biomarkers for myocardial when serial assays are performed and when they are performed several hours after the onset of chest pain. Depending on the timing of the study, a single CK-MB and troponin I drawn early after the onset of chest pain may have a sensitivity of only 34% and 40%, respectively, whereas serial assays and assays drawn late (>12 hours) after the onset of chest pain have sensitivities that approach 90% (6).

A typical approach to the patient who presents with chest pain and the concern for myocardial injury would be to draw CK-MB and troponin cardiac enzymes at presentation. If positive, there is a high likelihood of myocardial damage and appropriate therapy should be initiated, if not already started

based upon other data. If the initial study is negative, and there remains a high likelihood that the chest pain represents myocardial ischemia, serial enzymes should be performed over the next 24 hours. Important in the use of cardiac biomarkers is the recommendation that patients with a very low probability for myocardial ischemia should not undergo cardiac enzyme testing because of the possibility for a false-positive result leading to unnecessary testing (7).

CARDIAC IMAGING AND STRESS TESTING

Two-dimensional transthoracic Doppler echocardiography (TTE) is an important diagnostic study when directed based upon history, exam, and ECG findings. The utility in a patient with no risk factors for myocardial ischemia, a normal exam, and normal ECG is far less helpful. From the list of potential

Figure 64.5. Acute pericarditis. PR depression represents reciprocal atrial inflammatory changes in all leads except AVr where there is PR elevation as the vector of injury is directed upward and to the right. Ventricular injury current is directed down and leftward leading to ST elevation in most leads except AVr. (Reprinted from Goldberger AL. *Myocardial Infarction: Electrocardiographic Differential Diagnosis*. 4th ed. St Louis, MO: Mosby-Year Book, 1991, with permission from Elsevier.)

Figure 64.6. Digitalis effect (top) and digitalis toxicity (bottom). The typical ST segments have a scooped-out appearance. With digitalis toxicity (bottom), arrhythmias are common. In this case, the underlying rhythm is atrial fibrillation. The group beating is consistent with junctional tachycardia typical for digitalis toxicity. (Reprinted from Goldberger AL. *Clinical Electrocardiography: A Simplified Approach*. 4th ed. St Louis, MO: Mosby-Year Book, 1991, with permission from Elsevier.)

Figure 64.7. ECG changes associated with hyperkalemia (A) and hypokalemia (B). Day 1 (A) represents high serum levels of potassium with no recognizable P waves and prolonged QRS. On Day 2, the potassium level has decreased, and the P waves return and QRS becomes more narrowed. The T waves are tented consistent with hyperkalemia and must be recognized versus ischemic T waves. Day 1 (B) with low levels of serum potassium, the T and U waves have merged, and by Day 4 as the potassium approaches normal, the ECG normalizes. (Reprinted from Mirvis DM, Goldberger AL. *Electrocardiography*. In: Zipes DP, Libby P, Bonov TO, et al., eds. *Braunwald's Heart Disease*. 7th ed. Philadelphia, PA: Elsevier Saunders, 2005, with permission from Elsevier.)

causes of myocardial ischemia, TTE will accurately diagnose the following:

- Hypertrophic cardiomyopathy
- Severe aortic stenosis
- Dilated cardiomyopathy

In some cases TTE may provide clues to the diagnosis, but in many of these diagnoses, the echocardiogram may appear completely normal.

Figure 64.8. Sensitivity of markers of myocardial ischemia according to length of time from onset of chest pain. CK-MB, creatine kinase MB isoenzyme. (From Zimmerman J, Fromm R, Meyer D, et al. Diagnostic marker cooperative study for the diagnosis of myocardial infarction. *Circulation* 1999;99:1671, with permission.)

- Anomalous left main coronary artery from the pulmonary artery
 - Diastolic color flow within the ventricular septum representing coronary collateral circulation
 - Retrograde flow into the left main coronary artery
 - Mitral regurgitation with a structurally normal mitral valve (ischemic mitral regurgitation secondary to papillary muscle dysfunction)
 - Segmental left ventricular systolic dysfunction
- Coronary artery fistula
 - Diastolic color flow in the chamber receiving the coronary fistula, that is, right atrium
 - Enlarged right atrium and right ventricle if significant left-to-right shunt.
- Kawasaki disease
 - Coronary aneurysms

Cardiac MRI (CMR) and CT are the tests of choice when evaluating for anomalous coronary arteries, coronary fistulae, coronary aneurysm and ostial CAD following coronary reimplantation.

The main objective of stress testing for myocardial ischemia is to unmask the mismatch between myocardial oxygen demand and myocardial perfusion. At rest, the supply of myocardial

blood flow may be sufficient compared to the myocardial oxygen demand. However, with exertion, and increased demand, the amount of supply, i.e. myocardial perfusion may be inadequate and therefore ischemia is induced. Stress-induced ischemia may be detected by:

- ECG changes (ST depression)
- Segmental wall motion abnormality by echocardiography or CMR
- Perfusion defect by nuclear imaging or CMR

The role of stress testing in this population is less well defined. For the most part, stress testing is most sensitive and specific when the heart is structurally normal heart at rest, defined as a normal ECG with normal myocardial perfusion and wall motion at baseline. Therefore, a change in myocardial perfusion with stress will more clearly define the differences between normal and abnormal. In patients with a structurally abnormal heart (hypertrophic cardiomyopathy) or abnormal ECG (left bundle branch block [LBBB]), the ability to detect true myocardial ischemia with stress becomes much less accurate.

Additionally, when the diagnosis is nonatherosclerotic fixed CAD, a negative stress test may not clearly define the

TABLE 64.1

Strengths and Weaknesses of Various Stress Testing Techniques for Detecting Myocardial Ischemia

Technique	Strengths	Limitations
Exercise ECG	Low cost, short duration High sensitivity in three-vessel or left main CAD Provides useful prognostic information (e.g., ischemia at low workload)	Suboptimal sensitivity Low detection rate of one-vessel disease Nondiagnostic with abnormal baseline ECG Need to achieve $\geq 85\%$ of maximum heart rate for maximizing accuracy
Exercise or pharmacologic nuclear perfusion imaging	Higher sensitivity and specificity than exercise ECG Studies can be performed in almost all patients Quantitative image analysis	Suboptimal specificity because of artifacts Long procedure time when rest and stress both performed Higher cost than exercise ECG Radiation exposure Poor-quality images in obese patients
Exercise or pharmacologic stress echocardiography	Higher sensitivity and specificity than exercise ECG Comparable value with dobutamine stress Short time to complex examination Identification of coexisting structural cardiac abnormalities (e.g., valvular disease) Relatively lower cost than other techniques No radiation	Decreased sensitivity for detection of one-vessel disease Inability to image all of the left ventricle in some patients Highly operator dependent for image analysis No quantitative image analysis Poor acoustic window in some patients (e.g., chronic obstructive lung disease) Infarct zone ischemia less well detected
Magnetic resonance imaging (MRI)	High spatial resolution MRI coronary angiography promising Visualizing of subendocardial perfusion Pharmacologic stress procedure short No radiation	Inability to image patients with metal devices Difficult to image in setting of irregular heart rhythm <i>Motion artifact in absence of good breath-hold and respiratory gating</i> Coronary motion No large clinical studies yet published
Cardiac CT	Noninvasive coronary angiography to rule out significant coronary stenosis	Radiation exposure Cardiac motion artifacts Beta-blockers often required to reduce heart rate to < 60 beats/min Artifacts caused by coronary motion Prolonged breath-holding for scanner with < 16 -slice/s Images not generated in real time

TABLE 64.2 Causes of Myocardial Ischemia in Nonatherosclerotic CAD

Diagnosis	Treatment
Anomalous coronary arteries	Surgical repair with reimplantation or coronary bypass
Coronary spasm	Medical therapy with CCB, β B, Nitrates
Kawasaki disease	Medical therapy with β B, antiplatelets, anticoagulation, PCI
HCM	Medical therapy with β B, associated with intramyocardial bridging which may require myocardial release or coronary bypass
Aortic stenosis	Surgical replacement of the aortic valve, some may be candidates for balloon valvuloplasty
Coronary artery fistula	Transcatheter occlusion of fistula vs. surgical ligation
Thromboembolic CAD	Anticoagulation
Ostial CAD s/p reimplantation	Surgical repair of the ostium vs. coronary bypass

CCB, calcium channel blockers; β B, beta-blockers; PCI, percutaneous coronary intervention; HCM, hypertrophic cardiomyopathy.

risk of ischemia. Patients with anomalous CAD may exercise and participate in highly competitive sports with no symptoms of ischemia, but may still have intermittent ischemia that is unpredictable placing them at risk for sudden cardiac death. Stress testing in the population is frequently normal. Basso et al. (8) reviewed the clinical profile of young competitive athletes who suffered sudden cardiac death and at autopsy were found to have anomalous coronary arteries with origin of the coronary artery from the wrong sinus. They found that 6 of the 27 patients had premonitory stress testing, and that in all cases, the stress study was normal, including stress ECG and echo wall motion (2/2).

Therefore, the following patients in whom a high index of suspicion still exists after initial work up would benefit most from stress testing:

- Those with structurally normal heart
- Those who are able to cooperate with stress testing, whether medically or exercise induced

There remain many different types of stress testing to detect myocardial ischemia. Each test has strengths and weaknesses that depend not only on the test itself and imaging technique but also institutional experience. There are some institutions that clearly favor nuclear stress testing to echocardiography, or vice versa, and therefore become more proficient in one technique compared to another. A list of various techniques to detect myocardial ischemia are now available, each with their own set of strengths and weaknesses (Table 64.1).

TREATMENT

When patients present with myocardial ischemia from nonatherosclerotic CAD and ongoing chest pain, the immediate therapeutic interventions involve reducing myocardial oxygen demand with β -blocker therapy, antiplatelet agents, diagnostic testing to delineate the cause, and finally definitive treatment. Those with a history of KD presenting with chest pain and ischemic ECG changes are treated similar to typical acute myocardial infarction patients with thrombolytic therapy versus immediate cardiac catheterization and percutaneous coronary intervention. Other diagnoses such as anomalous CAD will require surgical intervention for definitive therapy. (see Chapter 32) (see Table 64.2)

SUMMARY

Myocardial ischemia remains rare in the pediatric population and in those with CHD. Historical features of myocardial ischemia are important to elucidate. With typical symptoms for ischemic chest pain, a high index of suspicion should dictate further testing. Definitive diagnostic testing with echocardiography, CMR and CT testing should confirm the diagnosis for the majority of those with a cause for myocardial ischemia. Cardiac catheterization should be performed when chest pain c/w ischemia is ongoing and when other diagnostic testing fails to find a cause for myocardial ischemia. General therapies include antiplatelet agents and reducing myocardial oxygen demand with β -blocker therapy. Definitive therapy is based upon the structural or functional abnormalities leading to myocardial ischemia and may involve additional medical therapies, catheter-based intervention or surgical repair.

Robert E. Shaddy ■ Francesco Parisi

Pediatric heart transplantation has been practiced for over 25 years. With the advent of the T-cell activation inhibitors such as cyclosporine, heart transplant success rates for pediatric and adult patients have improved to the point that the initially restricted ages and indications have expanded considerably. Infant heart transplantation has been performed for over 20 years (1), and infants, children, and adolescents with complex cardiac anatomic lesions are now routinely successfully transplanted (2–4). There have been additional immunosuppressant pharmacologic agents discovered since cyclosporine, and novel new agents are in investigational stages. The increasing experience and newer drugs promise even better long-term results. Currently, the half-life (50% still alive) for children transplanted in the early 1980s is approximately 11 to 18 years (4). Decades-long survival seems likely (5).

Over 300 heart transplant procedures are performed annually in pediatric patients in the United States. Many more infants and children and adolescents could benefit from heart transplantation each year. The rate-limiting step to making heart transplantation more widely available is donor availability. Matching of appropriate donors to recipients is a more complicated problem in pediatrics with fewer recipients awaiting transplant at any given time compared to adults. Thus, the logistics of matching the size, blood type, and location of donor and recipient are logistically more complex.

Organ transplantation in the United States is sanctioned by congressional mandate through the National Organ Transplant Act (NOTA). NOTA created the framework for the Organ Procurement and Transplant Network (OPTN). The contractor for the OPTN is the United Network for Organ Sharing (UNOS). The process of organ donor identification is required for all hospitals, and the management of organ donors is by government-regulated local agencies called OPOs (Organ Procurement Organizations). The decision to donate organs remains a voluntary process involving donor and family wishes. The current UNOS allocation algorithm has three status categories based on medical urgency. These categories are status IA, IB, and II. Status IA is for the sickest patients needing an urgent transplantation for survival. Waiting mortality is 17% to 25% for status I patients and remains a significant problem in all age groups (6,7). Even within the sickest pediatric wait-list group (status 1A), there is large variability in outcomes, with those requiring extracorporeal membrane oxygenation (ECMO) having the highest wait-list mortality (7,8). The synchronization of recipient need, donor availability, consent for organ donation, and finally organ transplantation is a modern medical miracle that represents the ultimate in human sharing.

At present, 1-year survival in excess of 85% and 5-year survival >70% can be expected following pediatric heart transplantation (Fig. 65.1). Catch-up growth and hemodynamic rehabilitation to normal childhood functional status is likely. The quality of life can be normal. Heart transplantation remains the only hope for children with lethal cardiomyopathy,

some forms of complex congenital heart disease, and some infants and children with failed surgical interventions. This chapter discusses the indications for heart transplantation, various phases of the transplant process (preoperative, early postoperative, and late), the immunosuppressive drugs, the role of heart and lung transplantation, and the issue of retransplantation.

PRETRANSPLANT EVALUATION

A large amount of historical, anatomic, hemodynamic, metabolic, immunologic, and psychosocial information is required before deciding whether or not a child is an acceptable transplant candidate (9) (Table 65.1). A comprehensive history and physical examination is mandatory, including age, height, weight, and body surface area. Since pediatric heart donors are matched with recipient size, accurate measurements of the recipient are critical and need to be continually updated in those patients who wait long periods of time and undergo changes in their height or weight. Cardiac diagnoses, including all previous surgeries, must be meticulously delineated, with particular attention to venous and arterial connections, since the surgeon will need this information in order to devise a surgical plan in those with complex congenital heart disease with abnormal connections. The use of extended donor heart and vessel retrieval and creative intraoperative techniques has resulted in successful orthotopic heart transplantation in children with abnormal situs and/or significant systemic and pulmonary venous anomalies (2,10). Immunization status should be determined, and if incomplete prior to listing for transplant, immunizations may be given as indicated by age (11,12). A history of malignancy, once considered to be an absolute contraindication to transplantation, may not preclude transplantation in selected patients (13,14). A thorough laboratory evaluation is necessary to determine liver and kidney function since severe, irreversible liver or kidney dysfunction would generally exclude the child from consideration for heart transplantation, although some centers may consider multiple organ transplants. An equally extensive infectious disease evaluation is necessary to exclude active infection, to determine potential latent infections such as cytomegalovirus (CMV) or Epstein-Barr virus (EBV), and to provide baseline data on susceptibilities that can be followed serially after transplant. An accurate and documented blood type is critical since this is usually the main compatibility factor used for donor/recipient matching.

Evaluation of the immune system is an important part of the pretransplant evaluation. Although it is common to check recipient and donor human leukocyte antigen (HLA) status, this information is not normally part of the decision-making process when determining donor suitability. Retrospective studies have suggested that HLA compatibility is rare but may lessen rejection and improve graft survival in heart

Figure 65.1. Actuarial survival for pediatric heart transplants performed January 1982 through June 2008. (From Kirk R, Edwards LB, Kucheryavaya AY, et al. The Registry of the International Society for Heart and Lung Transplantation: thirteenth official pediatric heart transplantation report—2010. *J Heart Lung Transplant* 2010;29:1119–1128, with permission.)

transplantation (15). In part due to the constraints of cold ischemic time (usually a maximum of about 4 hours) and the ongoing organ donor shortage, prospective HLA matching is not routinely utilized in heart transplantation. Panel reactive antibodies (PRA), a laboratory measure of preformed anti-HLA antibodies, are assayed to determine whether the recipient has any circulating anti-HLA antibodies. Recipients with circulating donor-specific anti-HLA antibodies before transplant have decreased graft survival when compared to those without these antibodies (16,17). Patients with a significantly elevated PRA before transplantation have traditionally undergone a prospective crossmatch between donor and recipient before acceptance of a donor organ (18–20). However, this can severely limit the donor pool available to a recipient and increases mortality waiting for transplant in those awaiting a compatible donor (16,20). Because of the significant difficulties associated with finding a compatible crossmatch in patients with elevated PRAs, multiple treatment modalities, including intravenous immunoglobulin, plasmapheresis, cyclophosphamide, and rituximab, have been utilized with variable degrees of success to try to decrease the PRA of highly sensitized patients (21–23). In sensitized adult patients awaiting renal transplant, rituximab has been shown to decrease HLA-antibody levels and thus expand the available donor pool for a HLA-compatible transplant (24). At the current time, there are conflicting data regarding the utility of the proteasome inhibitor, bortezomib, as an agent to reduce pretransplant donor-specific antibody (25,26).

With the exception of some infants with unoperated congenital heart disease (e.g., hypoplastic left heart syndrome [HLHS]), most children will require a cardiac catheterization before heart transplantation. Cardiac catheterization and angiography should be performed as part of the pretransplant evaluation by someone experienced in the diagnosis and treatment of pediatric cardiovascular disease and heart transplantation. Especially in patients with complex congenital heart disease, hemodynamic and anatomic assessments are critical for appropriate pretransplant evaluation. In addition to precise anatomic and hemodynamic definition, it is necessary to determine whether other pharmacologic, catheter interventional, or surgical options may be necessary prior to transplantation. Patients with univentricular physiology, particularly those who have undergone multiple palliative procedures, are

a unique group of patients whose pretransplant evaluation can be very complicated. For example, children after the Fontan operation may have many complications such as dysrhythmias, protein-losing enteropathy, cirrhosis, and/or low cardiac output that may bring them to transplant consideration.

Assessment of pulmonary artery anatomy, pressures and, when possible, pulmonary vascular resistance is critically important in the pretransplant evaluation of most children being assessed for heart transplantation. Severe, fixed elevation of the pulmonary vascular resistance is a contraindication to orthotopic heart transplantation because of concerns of acute posttransplant donor right ventricular failure. Both elevated transpulmonary pressure gradient and elevated pulmonary vascular resistance have been identified as risk factors for early mortality after heart transplantation (27). However, a previous multi-institutional analysis of risk factors for mortality in children >1 year of age at the time of transplantation did not find elevated pulmonary vascular resistance to be a risk factor (28). The current selection criteria for pediatric orthotopic heart transplant recipients exclude those patients with significantly elevated nonreactive pulmonary vascular resistance (3,9). In these patients who are denied orthotopic heart transplantation, other options such as heterotopic heart transplantation, heart/lung transplantation, or lung transplantation with repair of the congenital heart defect may be considered (29–31). Accurate evaluation of the degree of pulmonary hypertension may not be possible in those patients with either discontinuous pulmonary arteries or multiple sources of pulmonary blood flow, or in those with multiple branch pulmonary artery stenoses. Several agents have been shown to have both acute and chronic beneficial effects in lowering transpulmonary gradients and pulmonary artery pressures in adults and children. Response to these agents, including intravenous nitroglycerin, nitroprusside, prostaglandin E₁, dobutamine, enoximone, milrinone, in addition to inhaled nitric oxide, has been shown to predict outcome after heart transplantation (32–36). Mechanical circulatory support can also be considered in refractory cases (37). Children with restrictive cardiomyopathy appear to be at higher risk for development and rapid progression of significant pulmonary hypertension and thus require careful monitoring and possibly early consideration for heart transplantation (38,39).

Assessment of anatomy and function by a complete Doppler echocardiogram is a necessary part of the pretransplant evaluation.

TABLE 65.1 Routine Pretransplant Evaluation**Comprehensive history and physical examination, including:**

- Allergies
- Immunization record

Laboratory data

- Liver and kidney function tests
- Urinalysis
- Glomerular filtration rate
- Prothrombin time/partial thromboplastin time
- Complete blood count and differential
- PPD skin test
- Serologies for human immunodeficiency virus, hepatitis, cytomegalovirus, Epstein–Barr virus, *Toxoplasmosis gondii*, syphilis
- ABO type
- Panel reactive antibody

Consultation with dental service, or other services as indicated

- Cardiopulmonary data
- Cardiac catheterization and angiography
- Echocardiogram
- Radionuclide angiography
- Endomyocardial biopsy
- Electrocardiogram
- Chest radiograph
- Pulmonary function tests
- Vo₂ max

Psychosocial evaluation

- Possible relocation
- Long-term supportive care
- Parental substance abuse
- History of neglect or abuse

Cardiac magnetic resonance imaging may also be beneficial for defining anatomy and physiology. Radionuclide angiography may be superior to echocardiography in terms of quantitating the degree of systemic ventricular dysfunction. Endomyocardial biopsy may be indicated in certain instances, for example, to exclude active myocarditis or myocardial infiltrative diseases. Electrocardiograms and 24-hour continuous ambulatory electrocardiograms may be important in determining underlying rhythm, evidence of ischemia or previous infarction, and abnormal rhythms or intervals. A chest radiograph may be very useful for measuring the degree of recipient cardiomegaly to help in determining size limitations in potential donors. In older children, pulmonary function tests may be important, especially if there is any concern of chronic lung disease. In those who can cooperate, measurement of maximal O₂ consumption may be very useful for quantifying the degree of cardiorespiratory compromise the patient is experiencing. A significantly reduced maximal O₂ consumption <50% of that predicted for age may be considered evidence of compromise that should at least lead to consideration of heart transplantation as a therapeutic option (9,40). This diagnostic test may be much less useful in those children with heart failure who have undergone

the Fontan operation, since a significant number of patients in this group is unable to achieve maximal aerobic exercise capacity (41).

Psychosocial evaluation is a critical part of the pretransplant evaluation. A stable family support system that is emotionally and intellectually able to provide medications and posttransplant care is crucial to the success of the heart transplant. In many instances, it is necessary for the family to relocate to be in close proximity to the transplant center for the entire waiting period before transplantation and for 3 to 6 months after the transplant. This often provides additional stressors to the family. It is uncommon to have an absolute psychosocial contraindication to pediatric heart transplantation. However, a family history of noncompliance, substance abuse, or child abuse or neglect may be a relative contraindication to transplantation. In some instances in which the patient's parents have been determined to be incapable of handling the responsibility of caring for the child before and after transplantation, it has been necessary for a relative to take over those responsibilities (11). Financial needs and resources can vary considerably and should be thoroughly evaluated.

PRETRANSPLANT MANAGEMENT

Once a patient is under consideration for transplantation, every effort must be made to stabilize or improve the patient's clinical status. Since the waiting time for donors is unpredictable, patients may wait for long periods of time, during which time ongoing pharmacologic, catheter interventional, and occasional surgical treatments must be used as needed. Patients may deteriorate rapidly while waiting for a suitable donor, in which case, more invasive measures may be necessary to bridge the patient to transplantation.

The epidemiology of infant heart transplantation has changed through the years as the results for staged repair have improved and donor resources have remained stagnant. Heart transplantation, because of donor limitations, became consigned as primary therapy to those very few infants deemed unsuitable for staged reconstruction. Primary transplantation has remained available in some centers as a parental choice, and as the only solution for the occasional young infant with profound cardiomyopathic disease and inoperable complex congenital heart disease, including some tumors. Infants awaiting heart transplantation with ductal-dependent lesions (e.g., HLHS variants or other ductal-dependent lesions without good surgical options), are critically ill, chronically instrumented, and usually in an intensive care setting while they await transplantation (42,43). Since waiting times for donors has increased at many institutions, there are increased challenges and problems associated with keeping these infants stable, sometimes for several months, before a suitable donor becomes available (44,45). Initial efforts must be directed toward opening and maintaining patency of the ductus arteriosus through the use of continuous infusion of prostaglandin E₁. Once unrestricted ductal patency is achieved, therapy must be directed toward maintaining adequate systemic blood flow, sometimes through pharmacologic manipulation of the pulmonary vasculature (46,47). Some infants with HLHS and other ductal-dependent lesions have undergone percutaneous or surgical stenting of the ductus arteriosus in order to maintain ductal patency (48,49). The development of the so-called hybrid procedures has allowed surgical bilateral branch pulmonary artery banding and transcatheter stenting of the ductus arteriosus in place of a Norwood procedure (50). If necessary, heart transplantation after the hybrid procedure can be performed with acceptable results (51). Up to 50% of infants with HLHS may develop a critical restriction at the atrial septal defect level. These infants have excessive cyanosis and hemodynamic instability and

represent a high-risk group of infants who can be stabilized with interventional catheter procedures (52).

Heart transplantation has become a possible alternative to a high-risk Fontan operation in a strategy of staged palliation for single ventricle physiology. Heart transplantation should be considered as an alternative to Fontan completion in the decision-making algorithm for high-risk Fontan candidates, since rescue heart transplantation after early Fontan failure is associated with poor outcomes (53–58).

Patients with end-stage biventricular congenital heart disease represent a complex group for heart transplantation and require careful evaluation and management to ensure optimal perioperative and long-term outcomes. The vast majority of patients with biventricular congenital heart disease have undergone prior cardiac surgical procedures. Indications for transplantation in this subgroup are primarily progressive refractory heart failure following prior cardiac surgical reconstructive procedures. Contraindications to transplantation mimic those for other forms of end-stage heart disease (9,59,60).

Patients with heart failure secondary to ventricular dysfunction represent a significant proportion of children who are referred for heart transplantation. The natural history of dilated cardiomyopathy in children is quite variable; thus the optimal therapy for dilated cardiomyopathy and timing for transplantation in these children is unknown. Large, multicenter, randomized studies in adults with chronic heart failure have shown a significant improvement in left ventricular performance, symptoms, and survival in patients receiving angiotensin-converting enzyme (ACE) inhibitors and beta-blockers such as carvedilol or metoprolol when compared with placebo controls (61–64). Addition of beta-blockers to chronic heart failure therapy in some children (particularly those with a systemic left ventricle) may improve ventricular function, symptoms, and survival, thus delaying or even precluding the need for transplantation (65–68). ECMO has been used successfully in children as a bridge to transplantation, but remains problematic due to complications such as sepsis, bleeding, and neurologic injury (8,69–72). Options for mechanical support in children include miniaturized intra-aortic balloon pumps, ECMO, centrifugal pumps, and, more recently, both pulsatile ventricular assist devices (VADs) and axial flow devices (see Chapter 21). ECMO remains the most common form of mechanical support available and is the best option for acute decompensation. ECMO provides total cardiopulmonary support, can be relatively quickly accomplished, and allows the flexibility of peripheral and central cannulation (73,74). ECMO pumps, however, achieve nonpulsatile flow, and the circuit is complex. The incidence of bleeding and infectious complications is very high, and neurologic impairment with extended use is also common. ECMO also restricts patients' mobility, impairing physical rehabilitation. VADs have potential advantages over ECMO as a mechanical bridge (70). Pulsatile pumping may result in better tissue perfusion and specifically provides better recruitment of the microcirculation of the brain, lungs, and kidneys during extracorporeal circulation. In addition to improving a patient's hemodynamic status and reversing end-organ dysfunction, VADs can be partially or fully implanted and allow for physical rehabilitation to improve the patient's overall condition and likelihood for successful transplantation. Biventricular VAD support can effectively be used in small children as a bridge to heart transplantation and can be accomplished with low mortality and morbidity. Biventricular VAD support may offer an additional means to reverse extremely elevated pulmonary vascular resistance (37,75–79). However, the persistent high rate of morbidity emphasizes the importance of optimizing the decision-making process and, particularly, the timing of implantation. Patients with congenital heart disease and end-stage heart failure currently have a

limited number of options for long-term mechanical circulatory support. In recent years, significant advances have been made, and more devices are under development with some having already reached preclinical trials (80). Over the next few years, continued improvements in the field of pediatric mechanical circulatory support are expected, including the addition of new pediatric VADs, new magnetically levitated centrifugal pumps, and new low-pressure-drop hollow-fiber membrane oxygenators for ECMO.

DONOR ISSUES

Because of the ongoing donor shortage for pediatric heart transplantation, transplant cardiologists have made great efforts to maximize donor usage. Although optimal donors have normal cardiac anatomy and function, ideal size and blood type match, and minimal cold ischemic time, many successful pediatric heart donors are used that do not meet these ideal criteria (1). Some degree of both systolic and diastolic dysfunction in the donor heart can be tolerated (1,81). Studies have shown successful pediatric heart transplant outcomes after donor ischemic times as long as 8 hours, with no significant differences in outcomes between those with donor ischemic times >8 hours and those with donor ischemic times ≤90 minutes (82). Although the mechanism is unclear, the use of advanced-age donor hearts (>40 years of age) for appropriately sized teenage recipients carries a significantly higher 1-year posttransplant mortality than use of younger donor hearts (83).

The incidence of sudden infant death syndrome (SIDS) has decreased over the last 15 years (58). Still, SIDS is the third leading cause of death for infants with an estimated annual incidence in the United States of 0.54 per 1,000 live births. There has been no difference in clinical outcome between infants transplanted with a donor who died from SIDS compared to donors who died of other causes (1,84). Recently, the proportion of transplanted infant donor hearts where donor cause of death was SIDS has increased from just over 4% in 2000–2002 to nearly 9% in 2006–2008. This is possibly due to transplant centers' increasing confidence with the use of SIDS donors. Most recently, there is increased interest and investigation into the use of non-heart-beating heart donors after cardiocirculatory death as an additional source of donors for both adults and children (85,86). Increasing the number of donors remains an important goal to ensure that sick patients in need of transplant have that opportunity.

ABO INCOMPATIBLE HEART TRANSPLANTATION

The need for matching donors and recipients can lead to donor hearts that are not used and recipients who die waiting. Blood group matching is considered critical for heart transplantation. Since infants usually lack preformed blood group antibodies (isohemagglutinins), ABO incompatible heart transplants have been successfully performed in infants <1 year old, and occasionally older patients (87,88). Cardiac transplantation in infancy using ABO incompatible donors in the appropriate setting has now become an established protocol in many centers around the world. Those infants who received an ABO incompatible graft usually (but not always) fail to develop antibodies against the incompatible blood group epitope from the donor, while making antibodies normally to other incompatible blood groups (88,89). For example, a recipient whose

blood type is O and receives a heart from a B donor will later make antibody to blood group A but usually not to blood group B. This observation has been used as an example of B cell tolerance (90). This type of approach has resulted in improved wait-time survival of infants in some studies, but not in all studies (91,92). This difference may reflect the fact that donor hearts are still offered to ABO-compatible recipients before ABO-incompatible recipients in the UNOS system in the United States, but not in other systems. The 10-year outcomes of infants receiving ABO-incompatible heart transplants are virtually identical to ABO-compatible heart transplants (89). Thus, there appears to be no contraindication to listing all infants with low isohemagglutinin titers for ABO-incompatible heart transplant.

POSTOPERATIVE MANAGEMENT

General Considerations

The postoperative course after heart transplantation can be complicated by numerous unique issues. Potential complications relate both to the donor and the recipient. Myocardial injury and cause of death, donor versus recipient size, donor heart ischemic time, blood and tissue compatibility, infectious status of both donor and recipient, recipient diagnosis, and recipient clinical and psychosocial conditions may affect myocardial performance and postoperative course.

The effects of brain injury and death on myocardial performance have been investigated (81,93). The process of brain death leads to myocardial dysfunction and is often due to multiple factors: brain death itself may cause myocardial dysfunction; the donor cause of death (sepsis, trauma, etc.) can directly depress myocardial contractility; and the high catecholamine environment of stress or the pharmacologic support of the donor can lead to receptor downregulation. Although no specific correlation with survival has been demonstrated, it is common for many centers to accept some degree of donor heart systolic or diastolic dysfunction, either or both of which are often reversible after transplantation. Donor ischemic times in pediatric heart transplantation have been reported by many centers to increase the postoperative need for inotropic support but to not be a risk factor for 1-year mortality (82,94).

As described above, ABO-incompatible heart transplants have been successful in the 1st year of life before the onset of isohemagglutinin production. This practice requires particular attention to postoperative management including specific immunosuppression and transfusion protocols (87–89). In the adolescent age group, the number of patients with congenital heart disease who become transplant candidates after a long surgical and blood transfusion history is increasing. These patients represent an increasingly HLA-sensitized heart transplant population who require special consideration and often require pre- and postoperative immunomodulatory treatment (16,23,95). Many strategies have been tried to reduce this allosensitization before transplantation in order to optimize the opportunity for finding and transplanting an HLA cross-match-compatible organ. These strategies have included plasmapheresis, a procedure that involves extracorporeal removal and replacement of the entire plasma volume (containing antibodies as well as other proteins such as coagulation factors). Plasmapheresis requires placement of a large bore dual lumen catheter in a large central vein. This is often challenging in young children due to size of blood vessels, lack or minimal vascular access because of venous occlusions from previous catheters, and/or systemic venous anomalies. Exchange transfusions are often performed in children who are too small for vascular catheter placement and plasmapheresis. Additional

strategies include immunosuppressant medications (such as cyclophosphamide), intravenous immune globulin (IVIG), rituximab, or some combination of these (23,96,97). It has been known for decades that the presence of circulating anti-HLA antibodies before transplantation is associated with increased risk of rejection, graft vasculopathy, graft dysfunction, and death after transplantation (16,98–100). Injury to the graft may be acute with hemodynamic dysfunction or more chronic manifesting as chronic rejection or graft vasculopathy. Donor specific anti-HLA antibodies may be preformed due to allosensitization prior to transplant, or develop *de novo* at any time following transplant. The *de novo* development of anti-HLA antibodies after heart transplantation correlates with decreased long-term survival (101). Patients with *de novo* antibodies appearing more than 1 year following transplantation have the poorest survival (102).

Patients with congenital heart disease present unique perioperative problems related to their specific morphology, previous surgical procedures, and reconstructive surgery. Heart transplantation in children with an anatomic or physiologic single lung has been successfully performed, but pulmonary artery reconstruction increases risk for mortality (103–105). Heart transplantation for structural congenital heart disease with single ventricle physiology is associated with substantial early mortality, and transplantation after the acutely failing Fontan may be prohibitively risky (53). Fontan status remains a risk factor of mortality after heart transplantation with an expected 5-year survival barely approaching 70%, with particularly increased risk in those with evidence of pulmonary vascular disease (106). Tailoring of immunosuppressive therapy is a crucial issue in these patients since they are often immunocompromised from their failing Fontan physiology with protein loss, liver dysfunction, and low cardiac output. Heart transplantation outcomes for patients after the Fontan operation are better in those who require heart transplantation owing to ventricular dysfunction (rather than those with preserved ventricular function and failing Fontan circuit) and those without significant comorbidities such as hepatic cirrhosis or chronic malnutrition (57). Protein-losing enteropathy is a severe complication of Fontan physiology but can be improved by heart transplantation (55,58,107). Moreover, the long-term fate of protein-losing enteropathy after heart transplantation has not been completely elucidated, and recurrence of protein-losing enteropathy after heart transplantation has been reported.

Practical Considerations

Adequate monitoring of the postoperative heart transplant patient is essential. Recently published guidelines from the International Society for Heart and Lung Transplantation (ISHLT) for the perioperative monitoring of both adult and pediatric heart transplant recipients are detailed in Table 65.2 (108). Of these, standard pediatric monitoring would include all except assessment of pulmonary arterial wedge pressure and cardiac output via invasive catheters owing to concerns of catheter size and maintaining appropriate catheter position, especially in smaller recipients. However, continuous, direct measurement of pulmonary artery pressures is often monitored in pediatric patients, particularly those with elevated pretransplant pulmonary arterial pressures. Perioperative hemodynamic instability can be present and can be a result of multiple causes including graft reperfusion injury, inflammatory response after cardiopulmonary bypass, elevated pulmonary vascular resistance, and labile fluid status. Most patients can be supported with catecholamine infusions after transplant surgery and often benefit from an elevated heart rate to compensate for diastolic filling abnormalities. Temporary pacing is also used. Milrinone is often used to reduce pulmonary

TABLE 65.2

ISHLT Guidelines for Post-Heart Transplant Monitoring

Postoperative 12-lead ECG	Invasive arterial pressure monitoring
Right atrial or central venous pressure monitoring	Left atrial or pulmonary artery wedge pressure monitoring
Intermittent measures of cardiac output	Arterial oxygen saturation monitoring
Intraoperative transesophageal echocardiogram	Continuous assessment of urinary output

and systemic vascular resistance and potentially provides a non-adrenergic-receptor-dependent form of inotropic support. The donor right ventricle is not “prepared” to deal with elevation in pulmonary vascular resistances, and thus some degree of right ventricular failure is common and usually lasts for several days. Many agents, such as prostaglandins, prostacyclin, nitroprusside, inhaled nitric oxide, and others have been proven to be effective in these patients (36). In rare instances, right heart failure may be so severe that ECMO is required to support the circulation. Hemodynamic parameters, such as right-sided filling pressures and functional right ventricular assessment with echocardiography can be used to follow the course of right ventricular recovery and direct appropriate weaning from supportive measures. A preventive therapy with selective vasodilators as well as the availability of mechanical assist devices during and after heart transplantation can reduce deleterious effects of both transitional pulmonary hypertension and primary graft failure (109).

The early posttransplant period (<30 days) is the most hazardous. Primary graft failure and early morbidity are largely explained by recipient issues that increase perioperative risk (110). Review of the ISHLT Scientific Registry details several major risk factors for 1-year mortality (4):

1. Congenital diagnosis, on ECMO (relative risk: 2.86)
2. Congenital diagnosis, no ECMO (relative risk: 2.02)
3. Retransplantation (relative risk: 1.96)
4. Year of transplant: 1996–1997 versus 2002–2003 (relative risk: 1.68)
5. Year of transplant: 1998–1999 versus 2002–2003 (relative risk: 1.49)
6. On dialysis (relative risk: 1.66)
7. On ventilator (relative risk: 1.54)
8. Panel reactive antibody >10% (relative risk: 1.36)

Postoperative bleeding can be significant in children following heart transplantation. Causes are multifactorial and include previous congenital heart surgery necessitating extensive dissection, cardiopulmonary bypass, multiple suture lines, pretransplant heparinization for VAD or ECMO support, and poor preoperative nutritional status. Platelet and fresh frozen plasma infusions should be used as necessary to control hemorrhage, and recombinant factor VII may be useful for refractory bleeding. Volume resuscitation including packed red blood cells (preferably leukocyte-reduced and CMV negative) may be necessary, but should be administered with caution given the potential increased risk for alloimmunization from transfused leukocytes, which may express non-donor-matched HLA antigens. Patients with refractory hemorrhage or those demonstrating clinical evidence of cardiac tamponade should be surgically explored.

Acute renal failure occurs postoperatively in 3% to 10% of transplant recipients (111). Hemodialysis may be necessary for refractory fluid overload and oliguria in the presence of a rising serum creatinine. Multidisciplinary team management including nephrology consultation is often useful in this circumstance. Patients often develop systemic hypertension in the immediate postoperative period. This can be secondary to baroreflex-mediated hypertension, catecholamine dysregulation from low cardiac output before transplant, significant pre-existing renal injury, and newly initiated immunosuppressive medications such as corticosteroids or calcineurin inhibitors. Nitroprusside, calcium-channel blockers, ACE inhibitors, or a combination of these usually provides adequate blood pressure control. Recipient/donor size mismatching can also influence postoperative course. “Big heart syndrome” results when the donor size is significantly larger than the recipient. In the early transplant period, donor/recipient weight ratio mismatches of >2.0 may result in systemic hypertension syndrome with associated central nervous system symptoms including seizures and coma. Treatment consists of antihypertensive medication titration to achieve a normal blood pressure for age. An inappropriately small donor heart size has been associated with increased mortality, and a donor/recipient weight ratio <1 has been reported as a significant predictor of fatal postoperative heart failure (112). Postoperative pericardial effusions develop in 9% to 21% of adult recipients (113,114). The incidence in pediatric patients is unknown but is likely similar to adults and may, in part, be related to an increased pericardial volume created after a dilated heart is replaced with normal-sized heart that fills with fluid. Unless the effusion is hemodynamically compromising or there is a strong suspicion of an infectious etiology, the effusion usually does not require surgical or percutaneous drainage and can be monitored serially by echocardiography. Posttransplant sinus node dysfunction is common with a reported prevalence as high as 44% (115) and is likely related to myocardial ischemia and surgical manipulation. The ISHLT guidelines recommend pharmacologic treatment or pacing to maintain an adequate heart rate.

Immunosuppression is started in the perioperative period. Some institutions begin calcineurin inhibitors (cyclosporine or tacrolimus) just before the transplant operation. High-dose corticosteroids are given intraoperatively and continued for a brief period of time, after which they can be discontinued or decreased to a low-dose maintenance regimen. Additional immunosuppressive medications may be given postoperatively in the form of polyclonal antibodies directed toward multiple T-cell epitopes (antithymocyte globulin), or either chimeric or humanized monoclonal antibodies directed toward the interleukin 2 (IL-2) activation pathway (CD25) (116,117). Despite its success in achieving these goals, the universal use of induction therapy has been nonetheless limited due to mixed reports that it may have increased the risk for infection and posttransplant lymphoproliferative disease (PTLD), and there is no consistent evidence that it improves outcomes. Recent data suggest that induction strategies can be implemented without increasing early infection or PTLD risk (118). Other maintenance immunosuppressants include azathioprine or mycophenolate mofetil (MMF), and in a few selected cases, sirolimus.

Over the last 12 years, the incidence of rejection in the 1st year after pediatric heart transplant has decreased from about 60% to just over 40% (119). The peak hazard, or instantaneous risk, for rejection is around 1 to 2 months after transplantation (120). Older age at transplantation represents a risk for first rejection and a risk for an increased number of episodes of rejection within the first 6 months after transplantation. Infections occur in up to 25% of pediatric recipients during the early postoperative period, and 60% of these infections are bacterial (121). The most common bacterial pathogens reported are *Staphylococcus*, *Pseudomonas*, and *Enterobacter*.

cloacae (122). Bloodstream and pulmonary infections are most common, followed by urinary tract and surgical site infections (123,124). The ISHLT guidelines recommend perioperative antibiotic prophylaxis against skin flora, particularly *Staphylococcus aureus*, and, if donor infection is confirmed, additional targeted therapy against the potentially transmissible donor organism should be strongly considered.

Rejection: Diagnosis and Treatment

Institutional preference usually dictates whether endomyocardial biopsy or echocardiography is used as the primary rejection surveillance tool. Because of the inconvenience, greater technical challenges, and possible increased morbidity of biopsy in smaller children, there has been much interest in evaluating the role of echocardiography in children undergoing transplantation (125–131). Many quantitative echocardiographic parameters have been investigated, including various measures of systolic and diastolic function, changes in left ventricular wall thickness and mass, and development of mitral regurgitation or pericardial effusion. Doppler studies and tissue characterization have also been evaluated. Despite this interest, the controversy over the role of echocardiography is far from resolved. Furthermore, if endomyocardial biopsy is still considered the gold standard for diagnosing allograft rejection after heart transplantation (132–135), the value of routine surveillance biopsies is also controversial in children. In fact, many centers have discontinued routine surveillance biopsies after the 1st or 2nd year from transplantation. Many centers perform routine endomyocardial biopsy on infants significantly less frequently or not at all, instead depending on physical exam and echocardiogram to aid in diagnosis, and reserve biopsy only for clinical indications (136). With any clinical deterioration in the early postoperative period, evaluation of and treatment for rejection as the potential cause should be considered.

The need for noninvasive diagnosis of rejection has stimulated the ongoing search for biohumoral markers, such as B-type natriuretic peptide. The clinical relevance is still to be defined for all these markers (137–140).

Clinical evaluation of rejection is important but can be misleading, particularly in pediatric patients in whom infectious issues can mimic the presentation of rejection. The characteristic infiltration of the donor heart by lymphocytes leads to the diagnosis of rejection on endomyocardial biopsy (141). Histologically, cardiac allograft rejection and lymphocytic myocarditis can be very similar. There have been reports of positive viral genome in heart transplant endomyocardial biopsy specimens, suggesting viral myocarditis, in addition to improved outcomes in these patients if treated with IVIG for presumed myocarditis (142,143). Arrhythmias also may be a marker for rejection. The surface electrocardiogram may suggest atrial flutter or atrioventricular dissociation, but this observation may be attributed to the fact that the recipient atrial tissue contracts independently of the donor atrial tissue, and there may be two P waves present on the surface electrocardiogram that are not synchronous.

The vast majority of initial rejection episodes can be successfully reversed by high-dose corticosteroids alone or in conjunction with anti-T-cell antibodies. Corticosteroids as either intravenous methylprednisolone (10 to 30 mg/kg every 12 hours) or oral prednisone are the first line in rejection therapy. Humoral or antibody-mediated rejection (AMR) results from an antibody-mediated response to mismatched human leukocyte antigens present within the donor myocardium and vascular endothelium, and the number of mismatches may influence the speed and degree of rejection (144). Pathologically, this form is characterized by a lack of significant cellular

rejection on endomyocardial biopsy with characteristic histologic and/or immunohistochemical findings (145,146). It is often accompanied by left ventricular dysfunction and detection of donor-specific antibodies in the recipient serum. Treatment of AMR following heart transplant is focused on elimination of circulating antibodies, inhibition of circulating antibodies, suppression of B cells, plasma cell depletion, and/or complement inhibition, in addition to support of graft function, which is often impaired due to immune-mediated injury (147–149). Attempts to remove antibody are most commonly performed with plasmapheresis. Sedation may be required for catheter placement, which has risks if the patient is experiencing hemodynamic compromise from AMR. Fluid shifts, calcium and other electrolyte flux, and systemic reactions to blood products used for plasma replacement are other risks related to plasmapheresis and/or exchange transfusion. Immune apheresis (immunoadsorption) is an emerging modality to specifically remove circulating antibodies and immune complexes. Plasmapheresis is often accompanied by the use of high-dose IVIG for immunomodulation to block anti-HLA antibody activity and inhibit complement, as well as corticosteroids to further attenuate the negative effect of circulating antibodies. Therapies to specifically target B cells are often incorporated into treatment for AMR. Rituximab is a chimeric murine/human anti-CD20 monoclonal antibody that is utilized to deplete B cells and interfere with antigen-presenting cell activity to attempt to reduce the risk of recurrent AMR. While most reports have shown utility in treating AMR, all are small case series with different response rates and treatment protocols, combining various doses of rituximab with IVIG, steroid, and plasmapheresis. Serious infections are a notable side effect observed with rituximab therapy. Cyclophosphamide and MMF have also been used to directly suppress B-cell population. New therapies are constantly being sought since the current methods are not universally successful.

Immunosuppressive Medications

The class of drugs that inhibit T-cell activation are still the mainstay of immunosuppressive therapy. Cyclosporine was the first drug of this class to reach clinical utility in the early 1980s and in effect began the modern era of solid organ transplantation. Cyclosporine can be given initially intravenously in a dose of 0.03 to 0.1 mg/kg/h. When oral medications can be tolerated, the usual starting dose is approximately three times the intravenous dose or 2 to 6 mg/kg/day divided every 12 hours in older children, although higher doses are usually required in infants. Trough blood levels of cyclosporine must be monitored to insure efficacy and avoid toxicity. The therapeutic range for blood levels for the active compound, cyclosporine A, range from 100 to 350 ng/mL. Higher blood levels are usually maintained early after transplant, and tapered based on time posttransplant and clinical course. The bioavailability of cyclosporine is variable particularly in children, although the microemulsion preparations have improved bioavailability (150). Studies comparing cyclosporine with tacrolimus have suggested no definitive benefit of tacrolimus over cyclosporine in terms of reducing the incidence of rejection, although tacrolimus is now more widely used in pediatric heart transplantation than cyclosporine (4,151,152).

Tacrolimus acts at a different site in the IL-2 activation pathway of lymphocytes. Like cyclosporine it can be given intravenously. When given orally the starting dose is usually 0.05 to 0.1 mg/kg/day divided twice daily. Trough blood levels must be monitored. The usual therapeutic range is 5 to 15 ng/mL. The third agent in this class (T-cell activation inhibitors) is rapamycin (sirolimus). Sirolimus acts at a more distal site (target of rapamycin receptor) in the lymphocyte activation

cascade by blocking transcription of activation genes. Early experience with this medication as adjunctive or replacement therapy for calcineurin inhibitors have been promising (153,154). Sirolimus can inhibit smooth muscle proliferation and may have another advantage by inhibiting the process of cardiac allograft vasculopathy (CAV) (155). The dosing and monitoring of sirolimus in pediatric patients is not well defined. The usual starting dose is 1 to 2 mg/m²/day with levels of 5 to 15 ng/mL at present in heart transplant (156). Sirolimus is most often used in combination with a calcineurin inhibitor. However, sirolimus appears to be less nephrotoxic over the long term and has been successfully used as the sole T-cell activation inhibitor at a later stage in liver, renal, and most recently heart transplant recipients (157). Use in pediatric heart transplantation has been growing and has been positive for allowing reduction in calcineurin dose and in stabilizing and/or improving renal function (154,156). Everolimus is an inhibitor of the p70 S6 kinase, arresting the cell cycle of lymphocytes and vascular smooth muscle in the G1 phase, with additional immunosuppressive actions of IL-2 and IL-15-mediated T- and B-cell proliferation (158,159). Experience with everolimus in pediatric heart transplantation is limited.

Drug and food interactions are common with immunosuppressive agents. They should be carefully evaluated when starting new drugs, including even antibiotics or foods such as grapefruit.

Antiproliferative Agents

Historically, the most commonly used agent to block immune cell proliferation has been azathioprine. It is a nonselective inhibitor causing nonspecific bone marrow suppression. The usual dose is 1 to 2 mg/kg/day as a single daily dose and drug effect is monitored by the white blood count. The white blood count is usually maintained at >4,000/mL. Mycophenolic acid in the form of MMF inhibits the *de novo* pathway for purine synthesis. Since lymphocytes lack the salvage pathway, MMF can selectively block lymphocyte proliferation without the side effects of nonspecific bone marrow suppression. The improved selectivity compared to azathioprine may provide more effective immunosuppression (160). Because of these benefits, MMF has replaced azathioprine in most pediatric heart transplant protocols (4). Comparative studies in adult heart transplantation indicate an efficacy benefit for MMF over azathioprine (161). The usual starting dose of MMF in children is 600 mg/m², but absorption varies widely and higher doses may be required. In adults and adolescents, the dose of MMF is 3 g/day divided twice daily. The value of blood levels is controversial. The effective blood level for mycophenolic acid has been reported as 3 to 7 ng/mL (108). Methotrexate and cyclophosphamide have also been used in transplant recipients as adjunctive therapy for chronic or recurrent rejection (162,163).

Nonspecific Immunosuppression

Corticosteroids are potent immunosuppressive agents and are the first line of rejection therapy. Many centers also use corticosteroids as part of routine immunosuppression. In pediatric patients, the side effects of corticosteroids have encouraged most programs to attempt to discontinue routine oral steroids (164,165). The favorable experience in pediatric heart transplant with a corticosteroid-free maintenance protocol has led to its use with other pediatric solid organ transplant recipients. For significant rejection, methylprednisolone is usually given in a dose of 10 to 30 mg/kg every 12 hours intravenously for six to eight doses. A tapering dose may then be used to return

to usual maintenance oral doses of prednisone or discontinued depending on the policy of each individual program. The dose for maintenance of oral prednisone is in the range of 0.1 to 1 mg/kg/day.

All the current immunosuppressive medications do not lead to tolerance in humans, although they can lead to tolerance in experimental models. The transplanted graft must work for many decades in pediatric recipients. In order to reduce the burden of immunosuppressive drugs, the drive to develop tolerizing protocols for infants and children is pressing.

Late Follow-Up

The number of pediatric heart transplants performed worldwide markedly increased in the late 1980s and has since plateaued (4). The 5- to 10-year survival after pediatric heart transplantation can be achieved with good quality of life, although long-term concerns remain regarding rejection, infection, CAV, and complications of chronic immunosuppression, including malignancy, hypertension, renal insufficiency, as well as compliance with therapy (166). Since 1982, more than 8,500 pediatric heart transplantations have been successfully completed around the world (4). Of these 8,500, 24% were infant heart transplantations. The median survival time period for adolescents undergoing heart transplantation was 11.3 years and for infant heart transplantation was 18.3 years. These data indicate that the majority of the transplant recipients are surviving into their late adolescence and early adulthood. Given the improved health outcomes of the pediatric transplant recipients, research attention has begun to focus on growth, development (cognitive and psychosocial), and quality of life. Data from the Registry of the ISHLT also shows a different late survival for young child and adolescent recipients: When looking at conditional survival (i.e., subsequent survival for recipients who survived at least 1 year after transplant), both infants (age <1 year) and children (age 1 to 10 years) show a significantly lower risk of late mortality than adolescents (age 11 to 17 years). The median conditional graft half-life was >19 years for childhood recipients, and 15.2 years for adolescent recipients. In addition to immunologic factors that may provide an advantage for transplantation in the 1st year of life (167), reduced compliance to therapies in adolescent age patients may play a key role in determining these results. Many centers have reported that incomplete adherence with immunosuppressive therapy is the leading cause of late death in the adolescents (168). Reduced compliance to therapies in adolescent patients may play a key role in determining these results. Adherence is an important topic of investigation, particularly with adolescent transplant recipients, because of the negative impact it can have on their health status and mortality (169). Adolescent transplant recipients appear to be at particular risk for nonadherence for multiple reasons. First, the adolescent time period itself is a risk factor for nonadherence due to increased need during this period to fit in with their peer group and suppress any qualities that make them appear different (170). Additionally, body image becomes very important during this period as it is associated with peer acceptance, and the negative impact immunosuppressant therapy has on physical appearance may cause adolescents, especially girls, to stop taking the medication (170). Third, parents may expect adolescents to be more responsible for their own medical management and provide less supervision than they would with younger children (171). Fourth, there are data from pediatric cancer and the adult transplant literature that suggest patients become less adherent to medical regimen over time, which connotes increased rates for adolescence, given that many of them were transplanted as infants or younger children (172,173). Finally, the normal stressors that occur during adolescence can

interact with the stressors that are a result of the chronic illness to create psychological distress, which also increases the risk of nonadherence. The pediatric heart transplant recipient's ability to transition from childhood into a happy and productive adult life can be significantly affected by his or her cognitive abilities, learning experiences, sense of self, and emotions. Overall, the existing literature suggests that transplant recipients present with impairments in cognitive, academic, and neuropsychological functioning. While more information is available regarding pediatric transplant recipients' neurodevelopmental functioning, there are still limitations to the current understanding since few of the studies examined functioning beyond childhood. Attention to these factors is an important part of caring for these children. In this section, we discuss some of the important facets of long-term follow-up of pediatric heart transplant recipients, including routine health care maintenance issues and potential complications that may occur.

Health Care Maintenance

Vaccination is an important therapeutic approach to minimize infectious complications due to vaccine-preventable pathogens in organ transplant recipients (174). Nevertheless, vaccinations are commonly underused, and prospective randomized studies on their efficacy in transplant recipients are rare. Physicians should aim at complete vaccination coverage of both the patient and household contacts before transplantation, and vaccination should be performed as early as possible in the course of the underlying disease. Moreover, particular attention should be paid for complete vaccination of health care workers. All inactivated vaccines may be safely administered in transplant recipients, whereas most live vaccines are strictly contraindicated or should only be administered after a careful risk/benefit assessment. It is recommended to administer live vaccines such as measles, mumps, rubella (MMR) and varicella vaccine prior to transplantation (12). While MMR is the most effective after a year of age when maternal antibody has waned, it can be administered as early as 6 months of age for pediatric patients who may require transplantation. If transplantation has still not occurred by the time the baby is a year of age, the dose can be repeated. The second dose of MMR can be administered as soon as 4 weeks later. A minimum of 4 weeks between live-virus vaccine administration and transplantation is suggested. For patients who are incompletely vaccinated or unvaccinated prior to transplant, consultation with an infectious diseases specialist is recommended. While data regarding timing of vaccines after transplantation have not been fully evaluated, most centers restart vaccination at approximately 3 to 6 months after transplantation, when baseline immunosuppression levels are attained.

As vaccine-specific protective immunity may wane more rapidly on initiation of immunosuppressive drug therapy, a monitoring of specific immunity may help to identify patients who have lost protective immunity and may benefit from booster immunizations. If booster immunizations or primary vaccinations are applied after transplantation, they should be started at approximately 6 months posttransplantation to increase efficacy.

Generally, to reduce the risk of morbidity and mortality from these preventable diseases, it is important that physicians caring for pediatric transplant recipients update the immunization status of their patients. As with all children, pediatric heart transplant recipients can have fevers and require prompt evaluation for these. Fortunately, most acute febrile illnesses in these patients are not serious and can be managed safely in an outpatient setting (175).

Quality of Life and Rehabilitation

Children have very good quality of life and rehabilitation after heart transplantation. Key pediatric issues after transplantation include psychosocial support for patients and families with regard to school, growth, development, and future expectations (176). Heart transplantation in children aged 5 to 18 years seems to be associated with an ongoing deficit in parent-perceived physical health status (177). Most children grow at a normal rate after transplantation, showing normal onset and progression of puberty. However, catch-up growth may not be observed. This seems related to the types of heart disease, the age at transplantation, and the immunosuppressive regimen (178–180). Most children and adolescents have the capacity for healthy cognitive and psychological functioning after heart transplantation. Nevertheless, approximately 20% of pediatric heart recipients have abnormal neurologic examinations and 25% have emotional adjustment difficulties (181). Adolescent poor compliance or noncompliance represents part of these difficulties. Late rejection, associated with poor outcome, is often associated with nonadherence and adolescent age (169). Older children return to school and a more normal lifestyle after transplantation and express an improvement in the quality of their lives. Rehabilitation of the pediatric heart transplant recipient depends on the age of the patient and the degree of illness before and after transplantation. In contrast to the experience with adult heart transplant recipients, pediatric heart transplant recipients generally enjoy near-normal exercise capacity with low-normal oxygen consumption and just mildly reduced workload. Younger age at transplant is associated with greater exercise capacity (oxygen consumption). The persistence of some chronotropic incompetence may contribute to the lesser exercise capacity (182). Heart rate, systolic blood pressure response, and oxygen consumption all demonstrate significant incremental improvements with time after heart transplant, possibly providing supportive evidence for reinnervation of the allograft in many patients. In serial studies, deterioration in percent-predicted maximal oxygen consumption has been associated with a need for retransplantation owing to CAV. The utility of serial routine graded exercise tests in pediatric heart transplant recipients warrants further study, especially for its role in the detection of CAV (183). Exercise should be encouraged in this population. Benefits include improved blood glucose control, increase in bone density, and potential psychological enrichment. Return to age-appropriate activities including a physical education class can be achieved in the majority of patients within the first 6 months after transplantation (184). Patients with neurologic deficits may require special treatment programs.

Arrhythmias and Heart Rate Response

Significant arrhythmias after transplantation are relatively uncommon and when they occur may be indicative of graft problems such as rejection. Onset of supraventricular and ventricular tachyarrhythmias always raise concern of rejection (185), although pediatric heart transplant recipients appear to be more prone to tachyarrhythmias than adult heart transplant recipients, and they are not always associated with rejection (186). Ventricular arrhythmias also may be indicative of CAV. Symptomatic sinus bradycardia and heart block after transplantation requiring pacemaker placement have been described in a small percentage of children (187). Heart rate response to exercise and heart rate recovery after exercise in pediatric heart transplant recipients are consistent with autonomic denervation after transplant and suggestive of late autonomic reinnervation of these hearts (188). Previous studies in adults have demonstrated that parasympathetic reinnervation

is rather infrequent after heart transplant and occurs in only 5% to 10% of recipients (189). Sympathetic reinnervation occurs much more frequently, however, and has been described using both invasive and noninvasive approaches in adults (190). These include (a) measurement of norepinephrine levels from coronary sinus and heart rate response after intracoronary injection of tyramine; (b) kinetics after intravenous infusion of radiolabeled norepinephrine that includes coronary sinus catheterization; (c) histologic evidence of nerve endings on endomyocardial biopsy tissues using special staining; (d) scintigraphic techniques such as single-photon emission computerized tomography or positron emission tomography imaging using radioisotopes; and (e) heart-rate variability studies (191–194). A study in neonatal heart transplant recipients at 9.5 ± 2.3 years after their transplant reported higher peak heart rate and better exercise performance compared with reports in other cohorts of pediatric (nonneonatal) heart transplant recipients (182).

Late Rejection

One of the most important factors in reducing the risk of and morbidity from rejection is to maintain regular and frequent routine office visits for all pediatric heart transplant patients. Evidence of rejection in infants and small children ranges from no symptoms to a wide variety of nonspecific symptoms including tachycardia, tachypnea, lethargy, irritability, and poor feeding. Physical signs are similar to those in adults, including jugular venous distention, organomegaly, new murmur, and gallop rhythm. Children who have no rejection in the 1st year after transplant may be at lower risk for hemodynamically compromising rejection late after transplantation. Also “biopsy-negative” rejection—at times presenting with severe left ventricular dysfunction and negative cellular or immunohistochemical abnormality on biopsy—can occur late after transplantation. These patients can improve with augmented immunosuppression including plasmapheresis, cyclophosphamide, antilymphocyte therapy, and agents suppressing antibody production, but their long-term outcome remain guarded (195). Either cellular rejection or AMR can present as recurrent or refractory. In these cases, treatment strategies can include several immunosuppressant combinations and total lymphoid irradiation (196). Generally, late rejection can be an ominous sign and may be predictive of graft loss. Episodes of late rejection with or without hemodynamic compromise always raise the concern of noncompliance.

Infection

Pediatric heart transplant recipients are at risk for serious and opportunistic infections, including bacterial, viral (especially CMV), and protozoal (*Pneumocystis*) infections, particularly in the first 6 months after heart transplantation when immunosuppression is greatest. Because of the significant postoperative risk of infection, many centers use some form of prophylaxis against fungal (nystatin), CMV (acyclovir or ganciclovir in recipients who receive organs from CMV-positive donors), and/or protozoal (trimethoprim/sulfamethoxazole) infections, although exact indication and duration of prophylaxis are unknown (108). The Pediatric Heart Transplant Study reported the time-related risk of “serious” infection and death in a large pediatric heart transplant population from 22 participating centers in the United States (121). The most common types of infections were bacterial in 60%, followed by CMV (18%), other viral infections (13%), fungal (7%), and protozoal (2%). The peak hazard for bacterial and fungal infections was in the 1st month after transplantation, whereas the peak hazard for viral infection was in the 2nd month after

transplantation, with the most common virus being CMV. Availability of ganciclovir and the development of assays for rapid diagnosis of active infection, such as the polymerase chain reaction (PCR) detection of viral genome, have reduced the risk of CMV disease. In contrast to adults in whom previous CMV exposure is common, fewer pediatric donors and recipients are CMV seropositive (CMV+), thus increasing the risk of CMV posttransplant infection in pediatric recipients. Often this infection consists of benign viremia and does not lead to clinically relevant disease. Because CMV disease can occur early after transplant and the perioperative morbidity can be significant, prophylactic and preemptive strategies to minimize or prevent CMV infection/disease have been developed. Prophylaxis consists of intravenous ganciclovir or oral valganciclovir initiated in the early postoperative period with a goal of preventing CMV infection. Preemptive therapy consists of close monitoring of recipient CMV status, either by quantitative PCR or CMV antigenemia, and initiating treatment when a previously CMV-negative patient becomes CMV-positive thereby minimizing transition of infection into significant CMV disease. Prophylaxis with intravenous ganciclovir, oral valganciclovir, or CMV immunoglobulin is commonly used by pediatric transplant centers for CMV-mismatched patients and has a survival benefit over nonprophylaxis. The recent ISHLT guidelines recommend initiating treatment with oral or intravenous ganciclovir or valganciclovir for CMV+ or CMV-mismatched pediatric recipients (108).

Identification of viral genome in the myocardium of pediatric transplant recipients, particularly if untreated with IVIG, appears to be predictive of adverse clinical events, including CAV and graft loss (142,143). The risk of all types of infections is very low by 6 months after transplant, but a low risk persists indefinitely. Exposure to pets is controversial, but most centers recommend avoidance of cat feces because of the risk of toxoplasmosis and avoidance of reptiles because of the risk of *Salmonella*. Although infective endocarditis is a rare complication after heart transplantation, most centers recommend endocarditis prophylaxis long-term after heart transplantation before dental, upper respiratory, gastrointestinal, and genitourinary tract procedures that are likely to cause bacteremia.

Malignancy, Epstein-Barr Virus Infection, and Posttransplant Lymphoproliferative Disorders

Increased risk of malignancy is a well-recognized complication after organ transplantation. In pediatrics, the vast majority are lymphoproliferative disorders and are often associated with primary infection with EBV (197,198). In contrast to adults, PTLTD is the major malignancy in pediatric patients after solid organ transplantation, while other neoplasms are rare. The incidence of PTLTD increases during the year after transplantation and varies between the different types of organ transplantation; high incidence has been reported for the thoracic organs and intestine (5% to 40%), whereas the incidence in kidney and liver transplant patients (1% to 10%) is lower (199). The pathology of early onset disease is usually polymorphic, whereas late expression, usually beyond 3 years, is often monomorphic and lymphomatous (120,197). First-line treatment remains the reduction of immunosuppression with variable clinical response (198). Monomorphic disease may require treatment with conventional chemotherapeutic agents. Since the vast majority of lymphoproliferative disorders are of recipient B-cell origin after heart transplantation, the use of the chimeric anti-CD20 monoclonal antibody, rituximab, has been successful (198). The development of quantitative EBV PCR on peripheral blood samples represents a useful technique for diagnosing and monitoring viral loads, but it is still unclear how to use this information to guide patient care (200,201).

FIGURE 65.2. Selected posttransplantation left coronary angiogram demonstrating proximal left anterior descending (LAD) lesion that appeared minimal by angiography but demonstrated prominent intimal thickening on intravascular ultrasonography (inset).

Another novel approach is cellular immunotherapy, whereby the patient is given infusion of EBV-specific cytotoxic T-cells (198). Reports of malignant neoplasia other than lymphoma are rare in transplanted children. These include squamous cell carcinomas and other skin cancers. Therefore, children should be advised to avoid excessive sun exposure and use sunscreen.

Chronic Rejection and Cardiac Allograft Vasculopathy

Cardiac allograft vasculopathy (CAV) is the major factor limiting long-term survival after pediatric heart transplantation. CAV is manifested pathologically by a diffuse and accelerated form of coronary disease consisting of myointimal proliferation that is concentric and involves the entire length of the vessel, including intramyocardial branches. Eventually, luminal occlusion occurs. There may also be a pronounced inflammatory component (202). The cause(s) of CAV has been an area of intense research for decades, and is still not ideally defined. Most investigators agree that CAV is primarily an immune-mediated disease, and thus can be considered a major manifestation of chronic rejection (203). Immunologic events interact with nonimmunologic risk factors, such as donor age, hypertension, and graft ischemia/reperfusion injury, in addition to recipient hypertension, hyperlipidemia, obesity, diabetes, smoking, race, and gender (204). CMV infection after transplantation also has been associated with the development of CAV. The final common pathway of these mechanisms is endothelial activation, a prothrombotic environment, and endothelial damage with subsequent diffuse intimal proliferation. Major risk factors for development of disease in children are older recipient and donor age, and two or more episodes of rejection in the 1st year (205), in addition to late rejection episodes and late pacemaker requirement (206). Patients suffering from severe late rejection or presenting with symptoms of high-grade atrioventricular block must be monitored

aggressively and should be evaluated closely for the presence or development of CAV.

The incidence of CAV in children is less than that in adults (66% of pediatric patients are CAV-free at 10 years after transplant), but recipient age has been significantly related to freedom from CAV; infants and younger recipients (<10 years old) have lower risk of CAV than adolescents (4). It is possible that pediatric recipients have less CAV than adults because of less persisting donor factors or because of less nonimmune risk factors. However, the actual incidence of CAV in children is probably being underestimated because of the lack of reliable methods for diagnosing and monitoring the disease. Because the cardiac allograft is not innervated, angina is an uncommon presenting symptom of CAV. Clinical symptoms, when present, are generally limited to congestive heart failure with allograft dysfunction, silent myocardial infarction, or sudden death. Coronary angiography is still the first modality for diagnosing CAV, although it is well-appreciated that this modality underestimates the incidence and severity of disease. Dobutamine stress echocardiography is a safe, noninvasive technique that may be useful in diagnosing and following CAV in children (207). Intravascular ultrasound provides an additional modality for detecting CAV also in pediatric heart recipients, but is not always predictive of outcomes (208–210) (Fig. 65.3). More recently, intracoronary Doppler flow measurement of coronary flow reserve (CFR) with adenosine is a good indicator of endothelium-independent vasodilator response in children after heart transplantation and may be performed with reasonable safety in pediatric heart transplant recipients. Reduced CFR after systemic or intracoronary application of adenosine is associated similarly with CAV based on biopsy and coronary angiography, which might be important in future studies for establishing a noninvasive diagnostic tool for CAV in children (211). The ideal management of CAV is unknown; intervention or surgical management has had limited utility while medical management has been disappointing. As stated earlier in this chapter, both sirolimus and everolimus have potential for preventing and/or treating CAV

(155,158,212). Coronary interventional procedures can be used in pediatric heart transplant recipients for palliation of CAV (213,214). Medical treatment has primarily been directed toward attempts to decrease the progression of the disease by using preventive measures and manipulation of immunosuppression (203). A reduction in the incidence of CAV has been found after treatment with statins in adult patients (215). In pediatric patients, pravastatin and atorvastatin have been found safe and effective to reduce total cholesterol and low-density lipoprotein, and retrospective studies suggest a benefit on reducing the incidence of CAV in children (216–218). Long-term studies are required to evaluate the effect of statins on the incidence of CAV and on growing organs. For this reason they must be used with caution particularly in young patients. Minimizing the use of steroids and tailoring immunosuppression to protocols with tacrolimus may be beneficial over cyclosporine or sirolimus in maintaining better lipid profiles. Whether statins, and in particular pravastatin, affect progression of CAV or aid in its prevention in children has not yet been conclusively proven (219). Nevertheless, the clinical use of statins is now common in most pediatric heart transplant centers. Unfortunately, the mainstay of therapy for established, severe CAV remains retransplantation.

Complications of Immunosuppression

Because two of the main functions of the immune system are fighting infection and tumor surveillance, all immunosuppressants put the patient at risk for infection and malignancy. Additionally, individual immunosuppressant medications have significant adverse effects, even when properly used in appropriate doses. Hypertension is a common complication after transplantation and may represent in part an adverse effect of cyclosporine or tacrolimus, particularly when used in combination with corticosteroids. The multifactorial etiology of hypertension in this population means that blood pressure control is often difficult to attain, and further research is essential if we are to optimize our management and limit the impact of complications (220). Catastrophic neurologic complications have resulted from severe postoperative hypertension and require urgent treatment. Chronic hypertension appears to be less prevalent in pediatric heart transplant recipients than in adults, but it is still a problem requiring treatment, even in centers using a steroid-sparing maintenance immunosuppressive protocol. Antihypertensive therapy in these children should be similar to that used for adults, including calcium channel blockers, angiotensin-converting enzyme inhibitors, and/or angiotensin-receptor blockers (108).

Neurotoxicity is another recognized complication of cyclosporine, occurring in as many as 10% to 25% of patients, with a peak in the early postoperative period. Symptoms include tremors, restlessness, dysesthesias of the palms and soles, seizures, and altered mental status. Cyclosporine and tacrolimus (calcineurin inhibitors) may cause acute and chronic renal insufficiency and monitoring for renal insufficiency in children should be lifelong. Renal insufficiency increases over time in pediatric heart transplant recipients. African American race, younger age at transplant, longer duration of listing, high level of calcineurin inhibitors, and renal insufficiency at 6 months after transplant are important risk factors for renal insufficiency at 5 years after transplant (221). These patients should be followed carefully with early referral to a pediatric nephrologist if they develop evidence of renal insufficiency. Individual susceptibility, including transforming growth factor β_1 gene polymorphism, could play a role in the long-term outcome of renal function in patients with calcineurin inhibitor-based immunosuppression (222). Strategies to minimize long-term exposure to calcineurin inhibitors may reduce the

prevalence of renal insufficiency in this vulnerable population (223,224). These strategies include dosage reduction of calcineurin inhibitors and the use of antiproliferative agents like sirolimus and everolimus (154,225,226).

A high prevalence of lipoprotein abnormalities has been described among pediatric heart transplant recipients (227). Again, the use of cyclosporine and steroids has been associated with this disorder. Therefore, the increasing use of lipid-lowering agents also in pediatric patients appears justified. Posttransplant diabetes mellitus is present in approximately 2% of pediatric recipients with cyclosporine-based immunosuppression, but in 8% of recipients with tacrolimus-based immunosuppression (228, 229). Diabetes may be related to reversible insulin resistance. Tacrolimus levels, HLA-DR mismatch, and older age at transplant may predispose to posttransplant diabetes. Gastrointestinal complications can also occur during the follow-up of pediatric heart transplant recipients. They include cholelithiasis, intestinal pneumatosis, and colitis (230–232). Sirolimus reportedly has less nephrotoxicity than cyclosporine or tacrolimus but has been associated with severe stomatitis and frequent elevations in cholesterol and lipid profiles (233). Sirolimus has growth factor antagonist properties and may cause marrow suppression particularly when used in combination with other agents that can suppress the marrow such as tacrolimus or MMF.

Miscellaneous

Infants with HLHS who undergo heart transplantation require extended reconstruction of their aortic arch. Of these, as many as 20% will develop coarctation of the aorta that may require treatment. Although surgical repair may be necessary in complex obstructive lesions, balloon coarctation angioplasty is a safe and effective treatment in most situations (234) (see Chapter 13). Severe tricuspid regurgitation secondary to valve damage from endomyocardial biopsies is an uncommon but potentially hemodynamically significant complication. Attempts to minimize the number of biopsies, careful placement of the biopsy catheter, or the use of a long sheath may reduce the incidence of this complication. Anemia is highly prevalent in children after heart transplantation. The etiology of this uncertain, but usually is not secondary to iron deficiency (235).

Retransplantation

Experience with pediatric heart retransplantation is limited. Nevertheless, in the most recent summary of the Registry of the ISHLT, the number of patients undergoing retransplantation has increased to 6% for recipients between 11 and 17 years of age (4). The most common indications for retransplantation are CAV, followed by acute rejection, chronic rejection, and intraoperative donor organ failure. Elective retransplantation can be performed with acceptable mortality. Intermediate outcome is similar to that of children undergoing primary heart transplantation (236,237). When retransplantation is performed in the setting of early primary graft failure, the results are quite poor and many investigators consider retransplantation in this setting inappropriate (237,238). Encouragingly, the outcomes following retransplantation after a long intertransplant interval are equivalent to the outcomes following primary transplant (236). The medical and pharmacologic issues after retransplant mimic those following primary transplant.

Heterotopic and Heart–Lung Transplantation

Experience with heterotopic heart transplantation in children is limited. The main indications for this procedure are primarily the presence of fixed high pulmonary vascular resistance

that precludes orthotopic heart transplantation, although some consider availability of an undersized donor or expectation of a certain degree of recipient heart recovery to be indications as well. One- and five-year actuarial survival rates have been reported to be as high as 83% and 66%, respectively. Thus, in selected patients, heterotopic heart transplantation may be considered an alternative, particularly when pulmonary vascular resistance is excessively high for orthotopic heart transplantation. Another alternative in this situation is heart–lung transplantation. The volume of pediatric heart–lung transplantation decreased significantly in the 2000s both in frequency and in survival rates (239,240). Thus, the ongoing role of this procedure in the management of irreversible pediatric cardiopulmonary disease remains uncertain. In general, the poor late survival after heart–lung transplant tracks the poor late survival seen after lung transplant alone. Another alternative that has met with some success in the setting of excessively high, fixed pulmonary vascular resistance in those patients with unrepaired congenital heart lesions is the performance of single-lung transplantation and repair of the congenital heart lesion (30).

Pulmonary Vascular Disease

CHAPTER

66

Pathophysiology of Pulmonary Hypertension

Marlene Rabinovitch

This chapter addresses the pathophysiologic mechanisms leading to pulmonary hypertension associated with congenital heart defects and other disease-related or idiopathic processes. Our evolving knowledge of fundamental mechanisms has led to new and improved treatments and holds great promise for the development of future therapies.

HEART DEFECTS WITH INCREASED PULMONARY BLOOD FLOW

High-Flow Congenital Heart Defects and Pulmonary Hypertension

As early as 1935, Brenner (1) observed different types of pulmonary vascular lesions in patients with congenital heart defects. A variety of physiologic factors appeared to contribute to the severity and rate at which vascular disease developed in patients with congenital heart defects (Table 66.1). In 1958, Heath and Edwards (2) suggested that there was a progression of structural changes (grades I through VI) (Fig. 66.1). Grades I and II, medial hypertrophy and intimal hyperplasia, respectively, were considered mild and probably reversible. Grades III and IV were, respectively, lumen occlusion from intimal hyperplasia and early to advanced arterial dilation. Grade III was thought to be, at best, partially reversible, but grade IV, irreversible. Grades V and VI were considered terminal changes, grade V being angiomatoid formation, and grade VI fibrinoid necrosis. The latter changes were identified most frequently in older children. Structural changes that predicted severe and fixed elevation in pulmonary vascular resistance were therefore more difficult to establish in infants and young children, although it was recognized that certain lesions, such as transposition of the great arteries with intact septum, but especially with a large ventricular septal defect (VSD) or a patent ductus arteriosus, were at high

risk. Curiously, there have been reports of late progression of pulmonary vascular disease in infants with transposition of the great arteries even after successful and timely surgical correction. Infants with a large VSD, especially an atrioventricular septal defect, also developed pulmonary vascular disease in early infancy; in the latter group, there were advanced changes observed even within the first 6 months of life. Patients with cyanotic heart defects who had large, surgically created systemic-to-pulmonary artery shunts were also at risk for pulmonary vascular disease. Several investigators tried to quantify the degree of medial hypertrophy, but their measurements did not correlate closely with the preoperative level of pulmonary vascular resistance or with its change postoperatively (3).

Structural Remodeling and Growth

Beginning in 1965, a new and quantitative method of analysis of the pulmonary vascular bed was developed that was particularly applicable to the study of infants and young children because it incorporated features of altered growth of the pulmonary circulation. This method was based upon extensive studies carried out using a technique of radiopaque barium–gelatin arterial injection of a postmortem lung specimen. It was observed from the postmortem arteriograms that the vessels are prominent in the newborn, whereas in the adult they are obscured by a dense background haze produced by the addition of many small intraacinar arteries not present at birth (4). On microscopic examination, three features of normal remodeling and growth of the pulmonary vascular bed were established (5). With increasing age, muscle is observed in arteries located more peripherally within the acinus. At first, nonmuscular arteries become partially muscular, and later they become fully muscularized. At birth, the muscularized arteries are thick walled, but within a few days, the smallest muscular arteries dilate and their walls thin to adult levels. When infants are 4 months of age,

TABLE 66.1

Factors Determining the Development of Pulmonary Vascular Disease in Patients with Common Varieties of Congenital Heart Disease

	Major Factors					Minor Factors		PVD
	$\uparrow P_{PA}$	$\uparrow P_{PV}$	$\uparrow Q_{PA}$	$\uparrow PO_{2PA}$	$\downarrow PO_{2SA}$	$\downarrow pH_{SA}$	Hematocrit \uparrow	
ASD, secundum	—	—	+	+	—	—	—	Unlikely
ASD, primum	—	±	+	+	—	—	—	Possible
TAPVC	+	+	+	+	±	±	±	Highly probable
Large VSD	+	±	+	+	—	—	—	Probable
With mitral disease	+	+	+	+	—	—	—	Virtually certain
TF	—	—	—	—	+	+	+	Unlikely until late
With Potts	+	±	+	+	±	—	±	Probable
TGA	±	±	+	+	+	±	+	Virtually certain
With VSD	+	+	+	+	+	±	+	Certain

ASD, atrial septal defect; TAPVC, total anomalous pulmonary venous connection; PVD, pulmonary vascular disease; P, pressure; PV, pulmonary vein; Q, flow; PA, pulmonary artery; SA, systemic artery; P_{PA} , mean pulmonary artery pressure; P_{PV} , mean pulmonary venous pressure; PO_{2PA} , oxygen pressure in pulmonary artery; PO_{2SA} , oxygen pressure in systemic artery; pH_{SA} , pH in systemic artery; Q_{PA} , flow in pulmonary artery. +, present; —, absent; ±, may or may not be present; TF, tetralogy of Fallot; VSD, ventricular septal defect; TGA, transposition of the great arteries.

Adapted from Nadas AS, Fyler DF. *Pediatric Cardiology*. Philadelphia, PA: WB Saunders, 1972:68.

this process has included the largest muscular pulmonary arteries and is complete. Arteries grow both in number and size, and they grow most rapidly in infancy. Although alveoli also proliferate, the ratio of alveoli to arteries actually decreases from the newborn value of 20:1 to the value of 8:1, which is achieved first in early childhood and which persists (Fig. 66.2).

Morphometric analysis of the lungs of patients with congenital heart defects reveals disturbed growth and remodeling of the pulmonary vascular bed (Table 66.2) (6). On postmortem arteriograms from infants with VSD, the axial arteries were dilated at the hilum but narrowed peripherally. On microscopic examination of the pulmonary vascular bed, muscle had extended precociously into normally nonmuscular peripheral arteries, regression of the perinatal musculature had

not occurred, and there was additional medial hypertrophy. Also, the peripheral arteries had not grown normally in that they were small and few. Alveolar differentiation and multiplication, however, were normal. Because there were no regional variations in the lung, it was feasible to apply the morphometric technique to analysis of lung biopsy tissue in assessing abnormal muscularity and evaluating arterial size and number (7).

Lung Biopsy

Lung biopsy studies indicated that the severity of altered growth and development of the pulmonary vascular bed correlated with the hemodynamic state. Three progressively severe

Figure 66.1. Heath-Edwards classification of pulmonary vascular changes. A: Grade I: medial hypertrophy. Elastin–van Gieson stain (EVG), original magnification, $\times 150$. B: Grade II: cellular intimal proliferation in an abnormally muscular artery. EVG, original magnification, $\times 250$.

Figure 66.1. (Continued) C: Grade III: occlusive changes. Medium is thickened as a result of fasciculi of longitudinal muscle, and vessel is all but occluded by fibroelastic tissue. EVG, original magnification, $\times 150$. D: Grade IV: dilation. Vessel is dilated, and medium is abnormally thin (arrow). Lumen is occluded by fibrous tissue. EVG, original magnification, $\times 150$. E: Grade V: plexiform lesion. There is cellular intimal proliferation (arrow); clustered around are numerous thin-walled vessels that terminate as capillaries in the alveolar wall. EVG, original magnification, $\times 95$. F: Grade VI: acute necrotizing arteritis. A severe reactive inflammatory exudate is seen through all layers of the vessel. Hematoxylin eosin stain, original magnification, $\times 250$. (From Wagenvoort CA, Heath D, Edwards JE. *The Pathology of the Pulmonary Vasculature*. Springfield, IL: Charles C. Thomas, 1964, with permission.)

stages are seen. With grade A, there is abnormal extension of muscle into small peripheral arteries, or, in addition, there is a mild increase in wall thickness of the normally muscular arteries (<1.5 times normal). These patients have increased pulmonary blood flow and increased pulse pressure but normal mean pulmonary artery pressure. Meyrick and Reid (8) showed from ultrastructural studies of lung biopsy tissue that this change is due to precocious differentiation to mature smooth muscle cells (SMCs) of the pericyte in the nonmuscular region of the artery and the intermediate cell in the partially muscular region. Because arteries become more muscular as they increase in size, it is tempting to speculate that, in the altered hemodynamic setting of chronic high flow and high pressure, “stretch” is the stimulus for SMC differentiation from precursor cells.

With grade B, as in grade A, there is increased extension of muscle, but, in addition, there is more severe medial hypertrophy of normally muscular arteries. When medial-wall thickness

is >1.5 but <2 times normal (mild grade B), pulmonary hypertension is usually present; when medial wall thickness is more than twice normal (severe grade B), pulmonary hypertension is invariably present and usually the pressure value is greater than half that of the systemic level. The medial thickness is due to hypertrophy as well as hyperplasia of preexisting SMCs and also to an increase in the intercellular connective tissue proteins.

With grade C, in addition to the findings of severe grade B, arterial concentration and usually artery size are reduced. Patients with these changes usually have a pulmonary vascular resistance of $>3.5 \text{ U}\cdot\text{m}^2$. When the artery number is less than half of normal (severe grade C), pulmonary vascular resistance values are often in excess of $6 \text{ U}\cdot\text{m}^2$. The basis for grade C is likely the failure of new vessels to grow normally, although some loss of arteries also may occur. Morphometric grades A and B are refinements of Heath-Edwards grade I; grade C is a new feature that also appears to be of important functional

Figure 66.2. Schema showing peripheral pulmonary arterial development through morphometric changes: extension of muscle into peripheral arteries, percent wall thickness, and artery number (alveolar–arterial ratio) as they relate to age. **Upper panel:** Normal development. **Bottom panel:** Abnormalities in all three features in a 2-year-old child with a hypertensive VSD. T.B., artery accompanying a terminal bronchiolus; R.B., artery accompanying a respiratory bronchiolus; A.D., artery accompanying an alveolar duct; A.W., artery accompanying an alveolar wall; ALV/Art, alveolar–arterial ratio. (From Rabinovitch M, Haworth SG, Castaneda AR, et al. Lung biopsy in congenital heart disease: a morphometric approach to pulmonary vascular disease. *Circulation* 1978;58:1107–1122, with permission.)

significance. Grade C may be found with Heath-Edwards grade I, is common with grade II, and is invariable with grade III. In fact, when grade III is seen, arterial concentration is generally half of normal or less.

Whether and to what extent abnormal growth and structural remodeling of the pulmonary vascular bed are permanent and result in persistent pulmonary hypertension can be determined best by correlating these features with

postoperative hemodynamic studies. We correlated the quantitative features of abnormal growth and remodeling of the pulmonary arteries and the qualitative changes described by Heath and Edwards with the hemodynamic behavior of the pulmonary circulation in the immediate postoperative period in the intensive care unit 1 day after repair and at the time of routine cardiac catheterization study 1 year later (9). Patients with grade A or mild grade B changes have normal pulmonary artery pressures in the early postoperative period or only a minimal degree of elevation. Most patients with more severe medial hypertrophy (i.e., severe grade B and Heath-Edwards I) have elevated values. The pulmonary hypertension is frequently labile and almost always can be controlled. The mechanism and treatment are discussed in the next section. Both the presence and the severity of pulmonary hypertension in the early postoperative period are increasingly predictable when there are more advanced changes on lung biopsy, that is, reduced artery number (grade C) and intimal hyperplasia (Heath-Edwards II and III) (Fig. 66.3).

One year after repair, however, patients operated on within the first 8 months of life tend to have normal pulmonary hemodynamics regardless of the severity of vascular changes on lung biopsy, as do all patients with severe grade B (Heath-Edwards I) abnormalities, regardless of their age at repair. Patients surgically corrected between 9 months and 2 years of life with grade C and Heath-Edwards II or III structural changes may have persistent elevation in pulmonary vascular resistance. This appears inevitable in patients operated on after the age of 2 years (Fig. 66.3).

Quantitative techniques have been applied successfully to the analysis of lung biopsy tissue prepared by frozen section to help the surgeon decide between a palliative and corrective procedure when preoperative hemodynamic data are borderline or difficult to obtain or to interpret. The ability to predict from biopsy tissue whether even mild elevation in pulmonary vascular resistance will be present postoperatively is of increasing importance, particularly in the consideration of patients for a Fontan procedure. Patients with tricuspid atresia who have had previous systemic-to-pulmonary artery shunts and those with single-ventricle and previous pulmonary artery bands are particular problems. We currently consider a biopsy showing severe grade C (less than half the normal number of arteries) and grade III or greater changes in 20% of vessels to indicate severe vascular disease that is unlikely to regress postoperatively and may preclude a successful result from closure of a VSD; severe grade B, medial wall thickness greater than twice normal, or grade II changes in any vessel may preclude a favorable result from a Fontan procedure. Even minor vascular changes on lung biopsy tissue (mild grade B)

TABLE 66.2 Structural Features Quantified in Congenital Heart Defects

Congenital Heart Defect	Artery Size	Artery No.	Extension of Muscle	Medial Wall Thickness
VSD	↓	↓	↑	↑
Hypoplastic left heart	N	↑	↑	↑
CA	N	N	↑	↑
TAPVC	N	N	↑	↑
TF	↓	N or ↑	N	↓ or ↑
PA	↓	↓	N	↓

VSD, ventricular septal defect; TF, tetralogy of Fallot; TAPVC, total anomalous pulmonary venous connection; CA, common AV canal; PA, pulmonary atresia; ↑, increased, above normal; ↓, decreased, below normal; N, normal.

Figure 66.3. A: Lung biopsy grade is correlated with mean pulmonary arterial pressure recorded the day after surgical repair. The dashed vertical lines separate the normal from the abnormally elevated pressure values, and the dotted horizontal lines separate the biopsy grades. Note that with the more severe Heath-Edwards changes on lung biopsy tissue, there is a trend toward a greater proportion of patients with elevated pulmonary arterial pressures and higher values. A, B, C, morphometric grades; m, mild, s, severe. N, I, II, III, Heath-Edwards grades; n, normal; *, no patients in this group; VSD, ventricular septal defect; DTGA, D-transposition of the great arteries; complete atrioventricular septal defect; (AVSD) complex, associated abnormality. B: Graph correlating lung biopsy grade with pulmonary vascular resistance 1 year after cardiac repair. Patients who underwent repair within the first 8 months of life, but not those operated on later, had normal pulmonary vascular resistance regardless of the severity of their structural changes. (From Rabinovitch M, Keane JP, Norwood WI, et al. Vascular structure in lung biopsy tissue correlated with pulmonary hemodynamic findings after repair of congenital heart defects. *Circulation* 1984;69:655–667, with permission.)

are associated with increased morbidity after the Fontan procedure, gauged by prolonged hospitalization, as a result of the need for increased ventilator support and drainage from chest tubes (unpublished observations).

Wedge Angiography

Techniques of wedge angiography have been developed to assess preoperatively the structural state of the pulmonary vascular bed. Changes that can be evaluated quantitatively, such as sparsity of arborization of the pulmonary tree, abrupt termination, tortuosity and narrowing of small arteries, and reduced background capillary filling, generally reflect advanced changes in the preacinar arteries of at least Heath-Edwards grade III severity. A technique has been described that allows quantitative assessment of abnormalities in a pulmonary wedge angiogram (10). An end-hole balloon catheter is directed to the origin of the axial artery of the posterior basal segment of the right lower lobe; the balloon is inflated, contrast material is injected, and the injection is filmed on biplane cineangiography. The rate of tapering of the arteries is assessed by measuring the length of a segment over which the lumen diameter narrows from 2.5 to 1.5 mm. More abrupt arterial tapering is suggestive of more severe changes in the intraacinar arteries, assessed both morphometrically and by the Heath-Edwards classification (Table 66.3 and Fig. 66.4).

Further studies revealed that there are several pitfalls and limitations in the interpretation of the pulmonary wedge angiogram. Pulmonary stenosis or previous placement of a pulmonary artery band, owing to poststenotic dilation, will give the impression of rapid tapering. With advanced vascular

disease, there is sometimes such extensive intimal hyperplasia that the vessel appears narrowed all the way from the hilum so that abrupt tapering is no longer apparent. In this situation, however, the background haze is absent and the pulmonary circulation time is usually prolonged. Technical abnormalities also can result in difficulties in interpretation. If the injection of contrast fails to fill the vessels all the way out to the pleura, the background will appear dark, and if the balloon does not completely occlude the vessel, the false impression of a dense background will be created owing to filling of capillaries and veins. Assessment of the circulation time depends on the exclusion of pulmonary vein stenosis and intrapulmonary shunting.

Intravascular ultrasound could be investigated to estimate the severity of pulmonary vascular disease at least in proximal vessels. Optical coherence tomography is a new technique that can resolve neointimal lesions in very small arteries and may hold greater promise, but has just recently been applied clinically to assess coronary stent stenosis (11).

Reactive Pulmonary Circulation

A major challenge in pediatric cardiology is to understand and control the reactive pulmonary circulation, which can be particularly problematic in the early postoperative period. The pulmonary hypertensive crisis, as it has been called, is thought to result from interaction of a hypertrophied and perhaps hypercontractile circulation with an injured vascular endothelium, with platelets and leukocytes that were exposed to postcardiopulmonary bypass and hypothermia and may more easily degranulate and release potent vasoconstrictor agents, particularly thromboxanes and leukotrienes. In recent

TABLE 66.3

Correlation of the Pathology, Physiology, and Angiogram in Pulmonary Vascular Disease

Grade	Pathology	Physiology			Wedge Angiogram
		Q_p	P_{PA}	R_p

studies, increased density of neuroepithelial bodies has been observed in the airways of patients at risk for this complication (12). The neuroendocrine cells, which are also oxygen sensors, contain bombesin and serotonin, agents known to be potent vasoconstrictors. There is also an increase in vasoconstrictor neuropeptide-containing nerves (13) (Fig. 66.5). Because most of the pulmonary hypertensive crises occur while weaning patients from the ventilator, it is tempting to speculate that swings in airway pressure might lead to degranulation of the neuroepithelial cells and release of the vasoconstrictor substances. Moreover, we have observed a striking

decrease in lung compliance accompanying the pulmonary hypertensive crisis.

In ultrastructural lung-biopsy studies in patients with congenital heart defects and pulmonary hypertension, alterations in endothelial cells support endothelial dysfunction as a cause of heightened pulmonary vascular reactivity and also relate endothelial dysfunction to the pathogenesis of progressive pulmonary vascular disease. On scanning electron microscopy, the endothelial surface of normal thin-walled pulmonary arteries has a "corduroy-like" appearance in that the cells form narrow, even ridges. In contrast, the endothelial

Figure 66.4. Left: A wedge angiogram shows slow tapering of the axial artery in a child with dTGA and normal pulmonary artery pressure (P_{pa}) and resistance (R_p). Approximate segment length between 2.5 and 1.5 mm internal diameter is marked off (arrows). Right: A wedge angiogram in a child with a VSD shows rapid tapering of the artery when there is increased P_{pa} and R_p . An approximate segment length between 2.5 and 1.5 mm internal diameter is marked off (arrows). Large arrow denotes takeoff to the right pulmonary artery. (From Rabinovitch M, Reid L. Quantitative structural analysis of the pulmonary vascular bed in congenital heart defects. In: Engle MA, ed. *Cardiovascular Clinics: Pediatric Cardiovascular Disease*. Philadelphia, PA: FA Davis, 1981, with permission.)

Figure 66.5. A: Neuroepithelial bodies (arrowheads) are seen as dark-staining regions (immunoreactive for serotonin) in airway of a newborn infant. (kindly supplied by E. Cutz.). B: Tyrosine hydroxylase immunoreactive perivascular nerve fibers (arrow) at the adventitial-medial border of an alveolar duct artery in a child aged 2 1/2. Scale bar = 50 μ m. Diagram on the right shows terminal bronchiolus (TB) and airways of respiratory unit accompanied by an innervated pulmonary artery (PA). RB, respiratory bronchiolus; AD, alveolar duct. Square indicates area shown in (B). (From Allen K, Wharton J, Polak J, et al. A study of nerves containing peptides in the pulmonary vasculature of healthy infants and children and of those with pulmonary hypertension. *Br Heart J* 1989;62:353–360, with permission.)

surface of hypertensive thick-walled pulmonary arteries has a “cable-like” texture in that the cells form deep, twisted ridges. The hypertensive endothelium may be predisposed to interact abnormally with marginating blood elements, such as platelets and leukocytes. This might result in the release of pulmonary vasoconstrictor substances and smooth muscle mitogens (14).

On transmission electron microscopy, the endothelium appeared to show heightened metabolic activity with an increased rough endoplasmic reticulum. The subendothelium of the muscular arteries is also abnormal in that there appears to be degradation and neosynthesis of the internal elastic lamina. This observation provided an important clue related to the discovery of heightened elastolytic activity in

the vessel wall associated with the initiation and progression of pulmonary vascular disease. Further studies were designed to try to identify what the products of increased endothelial metabolism might be. We hypothesized that, because endothelial cells produce von Willebrand factor (vWF, factor VIII), an increase in this protein may cause platelet adhesion, formation of microthrombi, and may result in the release of pulmonary vasoconstrictor substances and smooth muscle mitogens. Using an immunoperoxidase stain for factor VIII, hypertensive pulmonary arteries stained densely, whereas nonhypertensive vessels did not. Circulating levels of the factor VIII molecule, both the antigenic component (VIII:Ag) and the biologic, assessed as ristocetin-induced platelet

agglutination (VIII:rist) were measured. Although VIII:Ag levels were significantly higher in patients with congenital heart defects and elevated pulmonary artery pressure than in those with normal pressure, only a few patients showed a concomitant elevation in biologic activity. This finding indicated that the molecule being secreted was lacking in biologic activity; indeed, further biochemical analysis of the factor VIII molecule showed lack of the high-molecular-weight components (15).

Under conditions that aggravate the endothelial dysfunction (e.g., cardiopulmonary bypass), vWF biologic activity was markedly increased (16). This could account for the development of platelet fibrin microthrombi in the postoperative period and for abnormal release of vasoactive compounds causing increased vascular reactivity. Various regimens have been adopted to anticipate and manage postoperative increased pulmonary vascular reactivity that include monitoring of pulmonary artery and left atrial pressures, institution of nitric oxide (NO) therapy, and the institution of phosphodiesterase inhibitors such as sildenafil, if therapy is needed beyond the intensive care unit.

There is now convincing evidence that impaired production of NO appears at an early time point in patients with congenital heart defects (17). There also is evidence that production of the vasoconstrictor endothelin also might be increased in patients with pulmonary hypertension and congenital heart defects (18).

Almost all patients with high-flow congenital heart defects who are operated upon in a timely fashion, show a fall in pulmonary artery pressure and return to normal resting hemodynamics indicating resolution and regression of pulmonary hypertensive structural changes. This is supported by experimental studies carried out by our group and others as well as by anecdotal reports of resolution of severe pulmonary vascular disease in the remaining lung after single lung transplant. There are, however, a few patients who maintain a high level of pulmonary vascular resistance and are refractory to vasodilator therapy despite what appear to be mild vascular changes on light microscopy (medial hypertrophy), and others who develop rapidly progressive pulmonary vascular disease despite early diagnosis and timely intervention. For these patients, the prognosis may be not much better than for those with unexplained pulmonary hypertension (19).

Therapies for the patient with Eisenmenger syndrome have included chronic oxygen, anticoagulants, and palliative surgical procedures, including atrial septal defect creation and intravenous prostacyclin as well as, more recently, aerosolized, nebulized, or oral prostacyclin. In some cases, these measures have improved the quality of life and in others they have served as a bridge to a heart-lung transplant or surgical correction along with single- or double-lung transplant, including living donors. More recent addition of sildenafil and endothelin receptor blockers in this group of patients awaits the results of clinical trials, but is discussed later in this chapter, and in the subsequent chapter, with regard to patients with primary pulmonary hypertension.

Pathophysiology Based Upon Further Pathologic Assessments

Recent immunohistochemical studies have been carried out in lung-biopsy tissue from patients with congenital heart defects to elucidate mechanisms that are directly related to enhanced proliferation and migration of cells in the neointima with characteristics of SMCs. There is a progressive increase in the deposition of two matrix glycoproteins, tenascin, and fibronectin, in the media and neointima (Fig. 66.6). We previously related the increased expression of tenascin to vascular SMCs

and fibroblasts. Fibronectin has been related to increased migration of smooth muscle-like cells in the context of neointimal formation. There is evidence from other studies that the neointimal lesions are associated with increased expression of transforming growth factor beta and procollagen in addition to fibronectin (20). It is also proposed that endothelial cell proliferation and a form of angiogenesis are observed with plexiform lesions. The plexiform lesions in pulmonary hypertension appear to be derived from different clonal populations of endothelial cells compared with those observed in primary pulmonary hypertension where a single clone is usually found (21). More recently, we described an increase in the expression of the calcium binding protein S100A4/Mts1 in advanced lesions from patients with congenital heart defects causing pulmonary arterial hypertension (PAH) as well as idiopathic PAH (Fig. 66.7) (22). S100A4/Mts1 stimulates vascular SMC migration and proliferation, is produced in response to serotonin stimulation (23), and is enhanced when there is increased activity of the serotonin transporter (SERT). This is in keeping with studies indicating that a polymorphism causing increased activity of the SERT is highly prevalent in patients with PAH (24).

Experimental Studies Simulating High Flow and Pressure

In experimental studies, an aortopulmonary shunt surgically created in a growing piglet results in a progressive increase in pulmonary artery pressure associated with the development of structural changes similar to those seen in the clinical setting. Creation of large aortopulmonary shunts in dogs, particularly into a single pulmonary artery, resulted in more rapidly progressive pulmonary vascular changes. There are several other experimental models of high-flow congenital heart defects such as in sheep or calves after an aortopulmonary lobar anastomosis. In utero placement of an aortopulmonary shunt most faithfully reproduces the changes that might be expected to occur in the newborn with a left-to-right shunt when the pulmonary vascular resistance falls. In this model, the initial response to high flow induced from the time of birth experimentally appears to be angiogenic with high levels of vascular endothelial growth factor (VEGF) and its receptors, but later in association with the decrease in VEGF and decline in arterial number, the resistance becomes elevated (25).

Takedown of the shunts during the period of rapid lung growth resulted in regression of both structural changes and pulmonary hypertension (26). Regression of medial hypertrophy and muscularization of distal vessels has been shown in experimental studies following pressure off-loading (27). There are many common features linking the cellular and molecular pathophysiology of pulmonary vascular disease, regardless of etiology, that we have linked to elevated elastase activity and this subject is discussed at the end of the chapter.

HEART DEFECTS WITH INCREASED PULMONARY VENOUS PRESSURE

Vascular Changes

Although advanced pulmonary vascular disease is less likely to occur early in patients with congenital heart defects related to increased pulmonary venous pressure, Collins-Nakai et al. (28) reported greater than Heath-Edwards grade III changes in the majority of older children in their series with congenital mitral stenosis. In patients with total anomalous pulmonary venous connection, abnormal muscularization of the

Figure 66.6. Representative photomicrographs showing immunoperoxidase staining for tenascin-C (TN) (A,D,G), proliferating cell nuclear antigen (PCNA) (B,E,H), and epidermal growth factor (EGF) (C,F,I) in graded lung biopsy tissue sections. A–C: Vessel showing a typical grade IA lesion; D–F: Vessel showing a typical grade IC lesion; G–I: vessel showing a typical grade IIIC lesion. In low-grade lesions (A), modest TN immunostaining was evident in the adventitia. With medial hypertrophy, TN immunoreactivity became more prominent in the periendothelium (D), with the most intense immunostaining being apparent within the neointima of high-grade lesions showing occlusive neointimal formation (G). In the lowest grade of lesion, PCNA was negative (B), despite foci of EGF in the media. With medial hypertrophy, PCNA was expressed in the media (E), together with foci of EGF (F). With the development of higher-grade occlusive lesions, TN (G), PCNA (H), and EGF (I) co-localized to the neointimal cell layers. Note that TN and PCNA staining was performed on serial sections, whereas EGF detection was carried out on similar vessels within the same biopsy. Original magnification, $\times 40$. (From Jones PL, Cowan KN, Rabinovitch M. Progressive pulmonary vascular disease is characterized by a proliferative response related to deposition of tenascin-C and is preceded by subendothelial accumulation of fibronectin. *Am J Pathol* 1997;150:1349–1360, with permission.)

small arteries and veins was observed from birth, and more severe structural changes (i.e., Heath-Edwards grade III) were described in infants as young as 1 month of age. In infants with hypoplastic left heart syndrome, there is such severe medial hypertrophy of the small arteries and veins from birth that it must have developed in utero (29). In both adults and children with rheumatic mitral stenosis, Wagenvoort and Wagenvoort (30) observed increased medial-wall thickness of the pulmonary arteries.

In postmortem arteriograms of infants and children with congenital heart defects and elevated pulmonary venous pressure, the axial pulmonary arteries have a reduced lumen diameter throughout their lengths. On microscopic examination of the lung, there is severe extension of muscle into peripheral intraacinar arteries, which are normally nonmuscular, and failure of regression of the fetal musculature of the normally muscular arteries. The vessels, however, appear normal sized and are normal or slightly increased in number. The presence of pulmonary vascular changes in defects with high pulmonary

venous pressure and the capacity for these abnormalities to regress with improvement in hemodynamics may be relevant because the Norwood and other various staged surgical procedure for the treatment of hypoplastic left heart syndrome ultimately depend on the success of a bidirectional cavopulmonary shunt and a right atrial-to-pulmonary artery anastomosis or tunnel.

Experimental Studies

Pulmonary venous hypertension has been created experimentally by banding the pulmonary veins or by elevating left atrial pressure. LaBourene et al. (31) banded the pulmonary veins in newborn piglets and studied the pathophysiology of progressive pulmonary venous obstruction. After 1 week, they observed no change in pulmonary hemodynamics, but there was a striking decrease in compliance of the pulmonary veins. By 3 weeks, there was PAH without elevation in

Figure 66.7. Representative photomicrographs of human lung biopsy tissue after immunoperoxidase staining for S100A4/Mts1. **A:** Vessel from patient graded 0-IB showing normal pulmonary artery with no immunodetectable S100A4/Mts1. **B:** Vessel showing a typical grade IB lesion with severe medial hypertrophy but without immunoreactivity for S100A4/Mts1. **C:** An artery from a patient with grade IVC disease with occlusive neointimal proliferation and strong positive staining for S100A4/Mts1 particularly in the intima compared to the media of the vessel. S100A4/Mts1 was not detected in all cells and appears to be localized in a subpopulation of intimal cells. **D:** A plexogenic lesion from a patient with grade IVC disease with staining of the SMCs and sparing of the endothelial cells (arrows). Immunoreactivity for S100A4/Mts1 was present in the lung parenchyma at a similar level in all grades of pulmonary vascular disease. Original magnification, $\times 40$. (Reproduced from Greenway S, van Suylen RJ, Du Marchie Sarvaas G, et al. S100A4/Mts1 produces murine pulmonary artery changes resembling plexogenic arteriopathy and is increased in human plexogenic arteriopathy. *Am J Pathol* 2004;164:253–262, with permission.)

pulmonary venous pressure. By 6 weeks, further progression of pulmonary hypertension was associated with elevated pulmonary venous pressure (Fig. 66.8). At 1 week, ultrastructural changes in the veins occurred that consisted of fragmentation of elastin and a phenotypic switch in medial SMCs in which they appeared to be more synthetic and migrating toward the subendothelium (Fig. 66.8). By 3 weeks, pulmonary venous hypertension developed and there was already evidence of intimal proliferation. By 6 weeks, there was an increase in collagen in the walls of the pulmonary veins. This study suggested that pulmonary hypertension may be the first sign of pulmonary venous obstruction and that elevation of pulmonary venous pressure is associated with considerable structural remodeling.

HEART DEFECTS WITH DECREASED PULMONARY BLOOD FLOW

Structural Features

In patients with congenital heart defects causing low pulmonary blood flow, hypoplasia of the pulmonary arterial musculature is observed, and in those in whom the hematocrit is particularly elevated, thromboemboli can occur. The creation

of systemic-to-pulmonary artery shunts may improve the hypoplasia, but secondary to abnormally high flow and pressure, medial hypertrophy and intimal hyperplasia also could ensue. Studies suggest that the potential for growth of the central pulmonary arteries is correlated with the proportion of elastin in the media, and the same may be true for the intrapulmonary vessels (32).

On postmortem arteriograms in patients with decreased pulmonary blood flow, the axial arteries are abnormally narrow in lumen diameter (33). The background haze also may be reduced, as in patients with pulmonary atresia and intact ventricular septum. On microscopic examination of the lung from patients with pulmonary atresia and intact ventricular septum, the intraacinar pulmonary arteries are abnormally thin walled, small, and few in number. In patients with tetralogy of Fallot, these vessels are normal or decreased in muscularity, normal in number, and small (34). Alveolar development is impaired in patients with decreased pulmonary blood flow, and this is reflected mostly by a reduction in alveolar number. Patients with tetralogy of Fallot and associated pulmonary atresia form a special subgroup in which the relative distribution of central pulmonary arteries and aortopulmonary collaterals determines peripheral pulmonary vascular structure. In patients with tricuspid atresia, the structural state of the pulmonary vascular bed is variable, depending on whether pulmonary blood flow is increased or decreased.

Figure 66.8. A: Pulmonary artery pressure (Ppa, upper panel) and pulmonary capillary wedge pressure (Pcw, lower panel) in banded and sham-operated piglets at 1, 3, and 6 weeks after banding. Values are averages of mean \pm SEM (n = six piglets per group at each time point). At 1 week, there was no change. At 3 weeks, there was a significant increase in Ppa, which preceded the further rise in Ppa, at 6 weeks ($*p < 0.01$; $^{\dagger}p < 0.05$). B: Transmission electron photomicrographs of representative pulmonary veins (PVs) from banded (right panel) and sham-operated (left panel) piglets at 3 weeks after banding (original magnification, $\times 14,131$) (inset original magnification, $\times 28,263$). Both pulmonary veins show apparent injury and lifting of endothelial cells and subendothelial spaces as a result of poor preservation during handling. Sham-operated PV displays on intact internal elastic lamina (IEL) and predominantly contractile-appearing SMCs (c) in media. In contrast, PV from banded piglet depicts complete breakdown of IEL into elastin fragments (Efg), a thickened subendothelium composed of collagen, extracellular matrix (ECM), and SMCs that appear to have migrated in from media, many of which have a synthetic-appearing phenotype (S) exemplified by a large amount of endoplasmic reticulum and a corresponding paucity of contractile filaments. C and S SMCs are better appreciated in insets. (Bar = 1 μ m). (From LaBourene JI, Coles J, Johnson DJ, et al. Alterations in elastin and collagen related to the mechanism of progressive pulmonary venous obstruction in a piglet model. *Circ Res* 1990;66:438–456, with permission.)

Experimental Studies

Levin et al. (35) created low pulmonary blood flow by banding the main pulmonary artery of fetal lambs. The changes in the lung that resulted consisted of diffuse hypoplasia of the musculature of the peripheral pulmonary vessels; those identified were small in caliber and few. Haworth et al. (36) ligated the left pulmonary artery in newborn piglets and demonstrated normal development of the intraacinar arteries owing to extensive anastomoses with bronchial arteries, but in the preacinar vessels, there was occlusive fibrosis of the lumen.

HYPOXIA-INDUCED PULMONARY VASCULAR DISEASE

Hypoxia and Pulmonary Vasoconstriction

The pulmonary hypertension that occurs in response to acute hypoxia is usually mild and rapidly reversible. Hultgren et al. (37) demonstrated an 18% increase in pulmonary artery pressure in men brought suddenly from sea level to high altitude (7,800 feet). There is much variability in individual response to hypoxia; some people hyperventilate and become mildly alkalotic, hardly increasing their pulmonary artery pressure at all, whereas others develop severe pulmonary hypertension with high-altitude pulmonary edema. Several theories have been proposed to explain high-altitude pulmonary edema. Endothelial swelling of small arteries occurs in some areas of the lung and causes high resistance, which results in diversion of excessive flow through small vessels, causing edema. Defective fibrinolysis with formation of microemboli has been reported, as has inadequate diuresis (38). Abnormal endothelial metabolism of factor VIII has also been described. There is increased circulating antigenic activity without increased biologic activity, suggesting that the high-molecular-weight components of the molecule may be associated with platelet microaggregates (39). Some studies suggest that high-altitude pulmonary edema may have an immune basis because it is associated with major histocompatibility complex HLA-DR6 and HLA-DQ4. The subset with pulmonary hypertension is associated with HLA-DR6 (40). The combination of acetazolamide, NO, and oxygen treatment has been successful in alleviating the symptoms of high-altitude pulmonary edema, and acetazolamide is also effective in preventing this complication.

Experimental Studies of Acute Hypoxia

Micropuncture has shown that both the small arteries and veins contribute to the acute hypoxic vasoconstrictor response. Studies by Hales et al. (41) suggested that prostaglandins mitigate the response to hypoxia, but the studies showed that the response to endothelial-derived relaxing factor is impaired. Recent reports revealed that with hypoxic vasoconstriction there is inhibition of a Ca^{2+} -activated depolarizing potassium channel. With chronic hypoxia, this channel may become activated as a relaxing mechanism.

The relationship between acute hypoxic vasoconstriction, the sustained pulmonary hypertension, and structural changes in the pulmonary vascular bed induced by chronic hypoxia is not known. Experimental studies of unilaterally banding the pulmonary artery in chronically hypoxic rats support the hypothesis that some structural changes in hypoxia are influenced by an alteration in the hemodynamics of the pulmonary circulation and others are more direct effects of hypoxia per se (42). The direct effect of hypoxia

is associated with increased ornithine decarboxylase activity, an enzyme implicated in structural remodeling of pulmonary arteries (43).

CHRONIC HYPOXIA

Clinical Features of Chronic Hypoxia

In persons who live at high altitudes, there is chronic elevation in pulmonary artery pressure that is frequently reversible at least under conditions of rest with administration of oxygen or return to sea level (44). In a study by Arias-Stella and Saldana (45), postmortem lung tissue from persons who had been living at high altitudes was compared with that obtained from sea-level dwellers. Structural changes were found in the vessels in the high altitude lung specimens; the peripheral arteries were more muscular than normal and had decreased lumen diameters.

Children living in Denver (elevation 5,200 feet) have slightly higher mean pulmonary artery pressures than sea-level dwellers, and children living in Morococha, Peru (elevation 14,900 feet) have mean pulmonary artery pressures that are twice as high. Moreover, in the high-altitude residents, mean pulmonary artery pressure more than doubles with exercise, whereas it increases by only 50% in sea-level dwellers.

Experimental Studies

In animal studies, Tucker et al. (46) observed that the degree of reactivity to hypoxia or the level of pulmonary hypertension varied among different species according to the amount of smooth muscle in the pulmonary vascular bed. In the rat, the hemodynamic and structural responses of the pulmonary vascular bed to chronic hypoxia were studied. After just 3 days of chronic hypoxia, a sustained elevation in pulmonary artery pressure and resistance was measured even after the rats were kept in room air for several hours. This finding coincides with the time that structural changes in the pulmonary vascular bed appear, in particular, the extension of muscle into peripheral arteries that are normally nonmuscular. Over the ensuing 2 weeks of hypoxia, mean pulmonary artery pressure progressively rises to double control values (47). This increase is accompanied by right ventricular hypertrophy, further extension of muscle into peripheral arteries, medial hypertrophy of normally muscular arteries, and reduction in arterial related to alveolar concentration. In the large preacinar pulmonary arteries, the adventitia is thickened as the result of an increase in the number of fibroblasts and collagen, and the media is also thicker as a result of hypertrophy of SMCs and accumulation of collagen, elastin, and other extracellular matrix components such as tenascin.

Relative hyporesponsiveness to hypoxia of the female animal has been observed in a number of species. During recovery from chronic hypoxia, mean pulmonary artery pressure returned to near normal in rats exposed as adults but remained 50% above normal in animals exposed during infancy, correlating with more severe residual vascular abnormalities. Ultrastructural and biochemical studies in the rat have shown that regression of smooth muscle hypertrophy following return to room air is accompanied by an increase in the amount of elastin and collagen in the vessel wall (48). Thus, the vessel, although less muscular, is enclosed in a tight sheath, which may interfere with its compliance and its ability to grow. In studies by Kerr et al. (49), inhibition of collagen synthesis decreased chronic hypoxic pulmonary hypertension and vascular changes.

Stenmark et al. (50) took newborn calves to a simulated high altitude of 4,300 m and observed severe pulmonary hypertension with right-to-left shunting owing to the rapid development of suprasystemic levels of pulmonary artery pressure. There was striking medial hypertrophy and remarkable proliferation of a dense adventitial sheath, which, in large vessels, was sometimes seen to exhibit neovascularization (Fig. 66.9). Further studies showed striking synthesis of elastin in the pulmonary arteries of these neonatal calves. Most recent studies have implicated fibrocytes as key contributors to the remodeling of the pulmonary vasculature. It is believed that these “stem cells” that have characteristics of both fibroblasts and leukocytes (51) migrate into the vessel wall through the angiomata located in the expanding adventitia (52) (Fig. 66.10)

and there is also a population of stem cells in the adventitia that may expand under conditions of hypoxia (53). There is also evidence in this model that epigenetic factors may be controlling the expression of proinflammatory cytokines in the fibroblasts in this model and that the inflammatory response is critical to the evolution of the disease (54).

Studies in transgenic mice suggest that genetic factors might modulate the response to chronic hypoxia. For example, in the absence of hemoxygenase 1, there is reduced production of NO and its associated vasodilatory effects (55). Prostacyclin synthetase overexpression is protective against the hemodynamic and vascular changes of pulmonary hypertension (56). Serotonin has been implicated in the increased vasoreactivity of the fawn-hooded rat (57), and there is attenuated severity of pulmonary vascular disease in mice lacking the SERT gene (58). Overexpression of the SERT worsens hypoxia-induced pulmonary hypertension (59) as does haploinsufficiency of *bone morphogenetic protein receptor 2* (*Bmpr2*) (60) or dominant negative *Bmpr2* (61), although in both cases the degree of structural remodeling is relatively unimpressive. Haploinsufficiency of *Bmpr2* in cultured SMCs and in transgenic mice makes them more sensitive to the proliferative effects of serotonin (62). Epigenetic factors also appear to control signaling via *Bmpr2* (63) as well as reduced expression of the free radical scavenger superoxide dismutase seen in the fawn-hooded rat with pulmonary hypertension (64).

We have shown that mice overexpressing the calcium binding protein S100A4/Mts1 have mild pulmonary hypertension under room air conditions. Values are increased over control mice in hypoxia but the remodeling response also appears to be mitigated. We related this to increased production of fibulin-5 and thickening of the elastic laminae (65). Thus overexpression of genes that might worsen hypoxia-induced pulmonary hypertension appears to invoke compensatory mechanisms that protect against the remodeling response. Understanding why these compensatory mechanisms fail may be critical in appreciating why some patients develop rapidly progressive pulmonary hypertension.

Numerous studies have attempted to show how acute vasoconstriction or a direct hypoxic “injury” initiates the structural changes observed in the pulmonary arteries. There is convincing evidence that the high endothelin levels are causally related to hypoxic vasoconstriction and the subsequent initiation of vascular changes. In some studies, chronic hypoxia appears to decrease endothelial nitric oxide synthase (eNOS). Strategies proven effective in the treatment of chronic hypoxic pulmonary hypertension in rats include inhibition of 5-lipoxygenase activating protein as

Figure 66.9. An artery from the lung of a 2-week-old calf raised at a simulated altitude of 4,300 m from birth. Pulmonary artery systolic pressure was 100 mm Hg. There is marked medial hypertrophy and adventitial thickening with neovascularization (arrow). Elastic tissue stain, original magnification, $\times 400$. (Kindly supplied by K. Stenmark.) (top). In situ hybridization localization of tropoelastin mRNA in control and hypertensive vessels from neonatal calves. White staining over areas indicates tropoelastin mRNA labeling. In normotensive vessels (middle), labeled cells (35S-labeled T66-T7) were confined to the inner media. Minimal signal is noted in the outer vessel wall. In vessels from hypertensive animals (14 days of hypoxia) (bottom), intense autoradiographic signal was observed throughout the media, albeit in a patchy distribution. (From Prosser IW, Stenmark K, et al. Regional heterogeneity of elastin and collagen gene expression in intralobar arteries in response to hypoxic pulmonary hypertension as demonstrated by in situ hybridization. *Am J Pathol* 1989;135:1073–1088, with permission.)

Figure 66.10. Immunohistochemistry (brown peroxidase signal) revealed a greater number of *c-kit*⁺ cells (arrows) in the vessel wall of distal (A) and proximal (B and C) arteries from hypoxic animals compared with control animals. The *c-kit*⁺ cells (arrows) are localized contiguous to vasa vasorum in proximal vessels (B and C) and continuous to and within the vessel wall of vasa located in the adventitia (F). Scale Bar represents 100 μ m in A, D, and E, and 50 μ m in B, C and F. (Reproduced from Davie NJ, Crossno JT Jr, Frid MG, et al. 2004. Hypoxia-induced pulmonary artery adventitial remodeling and neovascularization: contribution of progenitor cells. *Am J Physiol Lung Cell Mol Physiol* 286:L668–L678, with permission).

well as inhibition of cyclic 3'-5'-guanosinemonophosphate-specific phosphodiesterase, and continuous infusion of NO. In other studies, activation of voltage-gated K channels (Kv2.1) by gene transfer or a metabolic activator inhibited chronic hypoxic pulmonary hypertension (66,67). Serine elastase inhibitors also effectively reduce chronic hypoxia-induced pulmonary hypertension and associated vascular remodeling (68). In addition, experimental studies suggest

that vascular smooth muscle growth inhibitors may be useful in preventing vascular disease. Heparin infusion will decrease the severity of hypoxia-induced vascular changes, presumably by decreasing smooth muscle hyperplasia. Most recently, rho kinase inhibitors have proven effective when administered even by inhalation, in preventing pulmonary hypertension and structural changes associated with chronic hypoxia (69–72).

LUNG DISEASE

Several factors may contribute to the pulmonary hypertension that commonly but not invariably accompanies severe parenchymal lung disease: the level of hypoxia and polycythemia, the degree of endothelial injury and subsequent imbalance in vasoactive mediators and vascular reactivity, the level of pulmonary venous pressure secondary to dysfunction of the hypoxemic left ventricle, and the nature and severity of the structural damage to the pulmonary arteries. Treatment of the lung disease will decrease the level of pulmonary artery pressure by eliminating the contributing causes and by allowing some regression of the structural changes. The latter, however, ultimately determines the level of pulmonary hypertension and the rate of development of right-sided heart failure.

Obstructive Lung Disease

In children, unlike in the adult population, obstructive lung disorders such as asthma are only rarely associated with the development of pulmonary hypertension. In patients with cystic fibrosis, however, cor pulmonale is common. When right ventricular hypertrophy and failure are observed, they generally reflect the degree of abnormal structural remodeling of the pulmonary vascular bed. The severity of the arterial changes tend to be patchy, reflecting the nature of the lung disease, but the venous changes are more uniform suggesting that they result from left atrial hypertension secondary to the left ventricular dysfunction.

Restrictive lung disease may occur in childhood from a variety of causes, and pulmonary hypertension is a common complication. Examples of such restrictive lung disorders are diffuse interstitial fibrosis (Hamman-Rich syndrome), bronchopulmonary dysplasia, radiation fibrosis and chemotherapy toxicity, infiltrative lung tumors, and collagen vascular disease. In the latter, pulmonary vasculitis may be important etiologically and is discussed separately. Reversal of the pulmonary hypertension generally depends on the ability to affect the course of the interstitial lung disease. Few structural studies have been done in patients with restrictive lung disorders. It has been proposed that, secondary to fibrosis of the alveolar septa, the loss of small alveolar wall arteries results in an increase in pulmonary vascular resistance, and as a secondary response there is hypertrophy of normally muscular arteries. In a study of the lungs from premature infants in whom bronchopulmonary dysplasia was a complication of severe respiratory distress syndrome, Rendas et al. (73) observed that, although the preacinar arteries had dilated appropriately, there was extension of muscle into normally nonmuscular peripheral arteries, which might explain the persistent pulmonary hypertension in these patients. In addition, although the number of peripheral arteries relative to alveoli was normal, the marked reduction in alveolar number suggested an absolute decrease in the cross-sectional area of the pulmonary vascular bed.

UPPER AIRWAY OBSTRUCTION

Severe upper airway obstruction from a variety of causes (Fig. 66.11 and Table 66.4) may be complicated by the development of pulmonary hypertension. In each case, the hypertension is not always a direct result of the degree of airway obstruction but seems to depend also on whether there is a central component, such as diminished ventilatory drive or general neuromuscular pharyngeal dysfunction. Many patients with upper airway obstruction have worsening of their symptoms with sleep; this worsening may be mechanical, such as

positioning of the head or it may be the result of a central mechanism. Although removal of the airway obstruction often results in prompt return to normal pulmonary artery pressure and resolution of heart failure, these symptoms can persist for some time perhaps because of slow regression of hypoxia-induced structural changes in the pulmonary vascular bed or persistent impairment of ventilatory drive.

The Pickwickian syndrome described in adults, consisting of hypersomnolence and obesity associated with pulmonary hypertension, also has been reported in children (Table 66.4). The obesity, through increased work of breathing, stresses the respiratory control system, and depending on its inherent sensitivity, hypoventilation may result, causing further retention and hypoxia, which contribute to the lethargy and cor pulmonale (Fig. 66.11). Mental retardation is often but not invariably associated with this syndrome. Damage to the respiratory center, either as a primary disorder (Ondine's curse) or secondary to trauma or other neurologic disease, also may result in cor pulmonale as a result of chronic intermittent hypoxia and hypercarbia. Although the pulmonary hypertension of sleep apnea in adults is in large part attributable to airway obstruction, in children, it is often the manifestation of an abnormal central mechanism. Increasing attention to the "metabolic syndrome" and systemic vascular disease has prompted us to investigate insulin resistance, which occurs with obesity and is also related to the development or progression of pulmonary hypertension (74).

Structural studies of the lung at postmortem have been carried out in patients with hypoventilation caused by damage to the respiratory center and in children with sudden infant death syndrome. In the former group, the degree of medial hypertrophy was compatible with hypoxia-induced pulmonary hypertension. Severe extension of muscle into peripheral arteries was observed in one-third of all patients with sudden infant death syndrome and in all "near-miss" infants in whom apnea was documented and who later died suddenly.

DISORDERS OF THE CHEST WALL

Neuromuscular disorders affecting the chest wall, such as Duchenne muscular dystrophy, poliomyelitis, Werdnig-Hoffman disease, and diseases affecting the vertebrae and rib cage, such as scoliosis, may so impair ventilation as to cause pulmonary hypertension. In patients with scoliosis, the heart and lungs have been studied at postmortem using morphometric techniques. Mild right ventricular hypertrophy has been described in association with medial hypertrophy of normally muscular arteries, increased extension of muscle into peripheral arteries, and reduced arterial number, changes ordinarily found in association with chronic hypoxia-induced pulmonary hypertension. Reduction in arterial number has been found both in patients with lobes having a reduced alveolar number and in those with a normal alveolar number.

PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN

Persistent pulmonary hypertension of the newborn (PPHN) may result from one of three causes: underdevelopment of the lung and pulmonary vascular bed as seen in congenital diaphragmatic hernia, maladaptation of the pulmonary vascular bed to extrauterine life as a result of postnatal stress, and maldevelopment of the pulmonary vasculature (e.g., alveolar capillary dysplasia) (Figs. 66.12 and 66.13).

Development of the Normal Perinatal Pulmonary Vasculature

Current studies are addressing factors that regulate the fetal growth and development of the pulmonary vasculature, such

as matrix molecules (fibronectin and tenascin), and growth factors including VEGF, fibroblast growth factor, transforming growth factor, bone morphogenetic proteins, and Wnts. The balance between proteases such as elastase and matrix metalloproteinases and antiproteases controls the response to growth factors in two ways. Proteolytic enzymes release growth factors from the extracellular matrix and they also influence the production of matrix molecules that interact with cells and can promote or repress the activation of growth factor receptors.

Vasoactive molecules also regulate pulmonary vascular development; for example, endothelin production is associated with cell proliferation, and NO and prostacyclin are associated with the suppression of cell growth. Transcription factors are being identified that control vascular SMC differentiation and the programming of constellations of genes involved in pulmonary vascular morphogenesis.

The mediators responsible for maintaining the increased pulmonary vascular tone in the constricted fetal circulation and for the normal fall in pulmonary vascular resistance in the newborn have been the subject of much study, both experimentally and clinically. Studies by Wang and Cocceani (75) in isolated peripheral pulmonary arteries from fetal and neonatal lambs showed that endothelin is a powerful vasoconstrictor and may be responsible for the increase in pulmonary vascular resistance in the fetus, but this may depend also on the availability of specific receptors and on basal tone. Endothelin is released by endothelial cells in culture when subjected to

Figure 66.12. Left: Schema showing normal arterial dilation during transition from fetal to neonatal circulation. When the lung is underdeveloped, the vascular bed is hypoplastic and abnormally muscular. When it is maldeveloped, the vascular bed is abnormally muscular; when it is maladapted, it has not dilated appropriately at birth. Right: Arteriogram showing a small right lung with a distorted and even smaller left lung. Arteries in both lungs are reduced in size and number. (From Kitagawa M, Hislop A, Boyden EA, et al. Lung hypoplasia in congenital diaphragmatic hernia: a quantitative study of airway, artery, and alveolar development. *J Surg* 1971;58:342–346, with permission.)

Figure 66.13. Lung micrographs from the left (A) and right (B,C) lungs of an infant with alveolar capillary dysplasia. A: Barium distends the lumen of a preacinar artery (A) but does not enter the anomalous vein to the left of the artery. Intraacinar arterial branches that contain barium are identified (arrowheads), but intraacinar veins and venules are distended with red cells, presumably forced ahead of the barium by the postmortem angiogram. Airspaces are lined by cuboidal epithelium, and no luminal capillaries are seen, all vessels lying centrally in the airspace walls. Hematoxylin and eosin, original magnification, $\times 90$. B: Intraacinar pulmonary arteries showing medial muscular thickening that forms a continuous layer, even in the smallest branch (arrowhead), which is 20 mm in external diameter. Media is demarcated by external and internal elastic laminae, stained black in this elastic stain. A bronchiole is identified (B). Elastic-van Gieson, original magnification, $\times 220$. C: Intraacinar arteries, the smaller measuring 60 μm in external diameter, with concentric intimal fibrosis; the latter is overlaid by arrowheads that mark the internal elastic laminae. The media is narrow in these branches, but the lumen (containing festooned endothelial cells) is the same size as in the similar-sized arteries seen in B. Elastic-van Gieson, original magnification, $\times 220$. (From Cullinane C, Cox PN, Silver MM. Persistent pulmonary hypertension of the newborn due to alveolar capillary dysplasia. *Pediatr Pathol* 1992;12:499–514, with permission.)

hypoxia. Dilator prostaglandins partially influence the fall in pulmonary vascular resistance because indomethacin retards but does not prevent the decrease observed with oxygen. Current thinking suggests that vasodilation of the newborn pulmonary circulation may be the result of increased production of NO (76) and repression of potassium channels (77). Studies by Belik et al. (78) also suggested that the mechanical properties of fetal pulmonary vascular SMCs differ from those of the neonate.

Underdevelopment of the Lung

Underdevelopment of the lung parenchyma and associated pulmonary vasculature is associated with congenital diaphragmatic hernia, hypoplastic or dysplastic lungs, scimitar syndrome, and oligohydramnios secondary to renal agenesis and dysplasia. Pulmonary hypoplasia is also a feature of prematurity, absence of the phrenic nerve, asphyxiating thoracic dystrophy, rhesus isoimmunization, and, experimentally, amniocentesis and smoking.

Pulmonary hypertension and right-to-left shunting from birth will result from hypoplasia of the pulmonary vascular bed (Fig. 66.12). Heightened pulmonary vascular resistance can be attributed to the impaired gas exchange (hypoxia, hypercarbia) in addition to the structural changes in the vessels. In infants with congenital diaphragmatic hernia, reversal of pulmonary hypertension has been achieved by using vasodilators, extracorporeal membrane oxygenation (ECMO) or high-frequency oscillation, and NO alone or in combination with phosphodiesterase inhibitors. Some infants with hypoplastic lungs that had been refractory to NO prior to ECMO demonstrated a beneficial effect of NO after ECMO. The expectation is that the reduction in pulmonary artery resistance will stimulate regression of vascular changes and maturation in growth of the pulmonary arteries. There is recent evidence that endothelin receptor blockade may be a useful strategy in congenital diaphragmatic hernia (79). In some cases, however, the lung hypoplasia might be excessive and stimulation of growth of distal arteries and alveoli may be inadequate. Dysplasias of the lung associated with PPHN, such as alveolar capillary dysplasia (Fig. 66.13), which may be familial in nature, are currently so refractory to treatment that a biopsy probably should be done to guide clinical management.

Experimental studies carried out in newborn lambs and rabbits have shown that heparin can stimulate remodeling of the pulmonary circulation. Accelerated maturation of the pulmonary circulation was achieved by inducing an increase in the number of peripheral pulmonary arteries relative to alveoli. Clinical data show that this therapeutic strategy might prove useful in inducing the growth of peripheral arteries, thereby reducing pulmonary vascular resistance (80). Most impressive is the use of NO to experimentally stimulate angiogenesis and growth of distal vessels as well as alveoli (81,82). This has also been achieved with recombinant VEGF (83) and an activator of soluble guanylate cyclase (84). More recently, bone marrow progenitor cells and mesenchymal progenitor cells or even conditioned medium have been used to stimulate growth of vessels and alveoli (85–87) (Fig. 66.14).

Maladaptation of the Pulmonary Vascular Bed

Perinatal stress, for example, hemorrhage, hypoglycemia, aspiration, or hypoxia may result in failure of dilation of normally muscular vessels and left ventricular dysfunction, both contributing to persistent pulmonary hypertension. Structural studies of the lung at postmortem in fatal cases of meconium aspiration suggest that there were antecedent pulmonary vascular abnormalities that exacerbated the postnatal pulmonary hypertension. The most striking feature is the presence of muscle in arteries that are small and peripheral in location and normally nonmuscular. The use of inhaled NO in clinical studies and L-arginine in experimental studies and strategies to maximize dilator effects attributable to cyclic guanosine monophosphate (GMP) by inhibiting phosphodiesterases with agents such as sildenafil have proven effective in lowering pulmonary artery pressure. Because GMP-increased production of endothelin may underlie the pathophysiology, the use of endothelin receptor blockade or endothelial converting enzyme

Figure 66.14. Either bone marrow stromal cell (BMSC) or BMSC-conditioned media (CM) treatment prevents vascular changes associated with pulmonary hypertension in hyperoxia-induced lung injury. **A:** Hyperoxia-exposed, phosphate-buffered saline (PBS)-treated newborn mice develop significant right ventricular hypertrophy that is significantly reduced by BMSC treatment. Data are expressed as mean \pm SEM ($n = 10$ to 12 animals per group). $*p < 0.001$, compared with the two normoxia groups and the hyperoxia group that received BMSC. **B:** BMSC treatment significantly reduced the medial wall thickness as compared with the hyperoxia group that received PBS treatment. Data are expressed as mean \pm SEM. $*p < 0.001$, compared with normoxia and the hyperoxia group that received BMSC. **C:** Representative pulmonary arterioles immunostained for α -smooth muscle actin, displaying a thickened smooth muscle layer in hyperoxia-exposed mouse lungs as compared with normoxic controls, and absence of muscularization on BMSC treatment. **D:** Similar to BMSC treatment, BMSC-CM treatment significantly reduced right ventricular hypertrophy in hyperoxia-exposed animals, and **(E)** significantly reduced medial wall thickness as compared with the hyperoxia group that received pulmonary artery SMC-CM. Data are expressed as mean \pm SEM ($n = 16$ to 18 animals per group). $*p < 0.0001$ versus normoxic groups or BMSC-CM treated groups. **F:** Representative small pulmonary arterioles, as in **(C)**. Solid bar scale represents $100 \mu\text{m}$ and all the panels are under the same magnification. (From Aslam M, Baveja R, Liang OD, et al. Bone marrow stromal cells attenuate lung injury in a murine model of neonatal chronic lung disease. *Am J Respir Crit Care Med* 2009;180:1122–1130 with permission.)

inhibition may prove beneficial, especially if specificity could be controlled to maximize dilatory activity. That is, endothelin A receptors and endothelin B constrictor (as opposed to endothelin B dilator) receptors should be targeted.

Maldevelopment of the Pulmonary Vascular Bed

Newborns in whom there is no apparent reason for persistent pulmonary hypertension are the most perplexing of all. Clinical studies suggested in some cases a relationship between maternal ingestion of prostaglandin synthase inhibitors and subsequent persistent pulmonary hypertension. In a study of infants with PPHN reduced expression of the gene for eNOS was reported (88).

Chronic hypoxia in pregnant guinea pigs and in pregnant rats will produce structural changes in the pulmonary vascular bed of the newborn. In lambs, the clinical syndrome has been produced by administration of a cytokine associated with inflammation, that is, tumor necrosis factor alpha. Relatively short periods of hypoxia in the fetal lamb will result in sustained elevation of pulmonary artery pressure and structural changes in the pulmonary arteries. In utero ligation of the ductus arteriosus simulates the structural changes and the initial hemodynamic profile of persistent pulmonary hypertension. In this model, increased lung preproendothelin and decreased (endothelin B) ETB receptors were observed (89). These features have been reported in the same experimental model in association with reduced expression of NO synthase. In addition, there is an elevation of cyclic GMP phosphodiesterase activity that would potentiate the effects of reduced NO. In this model, phosphodiesterase inhibitors have proven effective in reducing pulmonary hypertension. Endothelin receptor blockade has also been used to successfully treat an experimental model of pulmonary hypertension associated with prematurity (90). Structural changes in the contractile apparatus of the hypertensive pulmonary arteries, such as the reduction in myosin light-chain phosphatase, also could influence the response to vasodilators. There are promising studies in lambs using antioxidant (superoxide dismutase) along with NO in neonatal lambs with persistent pulmonary hypertension (91).

THROMBOEMBOLIC DISEASES

Clinical Features

Diagnosing thromboemboli as a cause of pulmonary hypertension requires a high index of suspicion in patients who have disorders in which the former are likely to occur (Table 66.5 and Fig. 66.15). For example, thromboemboli frequently occur in children who have ventriculoatrial shunts for hydrocephalus because of either clots dislodging from the end of the catheter or an abnormal fibrinolytic reaction of cerebrospinal fluid within the lung. Children with sickle cell anemia may develop pulmonary thromboses and infarctions. In endogenous areas, ova emboli due to schistosomiasis have been described. Fat emboli may occur secondary to trauma and also in association with collagen vascular disease. Tumor emboli may carry metastatic disease from the kidneys or other abdominal organs, or they may be present in association with infiltrative carcinomatous disease of the lung. Thromboembolic pulmonary hypertension is also associated with tumor chemotherapy. Deep vein thrombosis is also seen in children as a source of pulmonary emboli. Right-sided endocarditis and right atrial myxoma also may be sources of emboli. In the newborn and young infant, pulmonary thrombosis may be associated with sepsis

TABLE 66.5

Sepsis and/or dehydration
Right-sided endocarditis
Right atrial myxoma

and dehydration and portal or renal vein thrombosis, and it is seen with nephrotic syndrome. Thromboembolic pulmonary hypertension also can be associated with steroids. There is little direct evidence that oral contraceptives alone will cause the development of pulmonary vascular disease in women, but these compounds probably should be avoided, particularly in susceptible women, such as those with congenital heart defects and pulmonary hypertension. Diagnosis of the nature and severity of embolic phenomena can be established by chest radiography and lung scans, although occasionally angiography is necessary, and there have been advances in treatment by thromboendarterectomy (92). There are two factors that probably contribute to the pulmonary hypertension of thromboembolic disease: first, the structural damage and occlusive changes within the large and small arteries; and, second, the concomitant release of vasoactive substances, particularly from degenerating platelets, serotonin, or thromboxane.

The nature of the pulmonary vascular abnormalities in thromboembolic disorders has not been studied extensively in children, but findings can be expected to be similar to those described in adults. In postmortem pulmonary arteriograms of adult patients, some vessels show evidence of thrombi (seen as filling defects), and filling of the peripheral distribution of these vessels with contrast material is scant. Other areas of the lung, however, appear normal. Upon microscopic examination of the abnormally filled areas, fibrous intimal hyperplasia is observed, mostly eccentric in nature, in both the preacinar and peripheral intraacinar arteries. Some vessels show evidence of having been completely occluded and later recanalized. Microscopic examination of areas that appear normal on the arteriogram show intraacinar pulmonary arteries that are increased both in size and concentration, suggesting compensatory dilation and recruitment. Throughout the lung, there may be medial hypertrophy of muscular arteries, but this probably depends on the duration of the disease and the severity of pulmonary hypertension.

SICKLE CELL DISEASE AND OTHER HEMOGLOBINOPATHIES

There has been increasing recent attention given to the complication of pulmonary hypertension in patients with sickle cell disease (93) and other hemoglobinopathies such as thalassemia. This complication is now recognized as a significant risk factor for death (94). The cause goes beyond thromboemboli

Figure 66.15. A: Lung perfusion scan performed after injection of technetium-99m macroaggregated albumen in a teenage boy who, after an orthopedic procedure, developed deep vein thromboses and pulmonary emboli. The latter are visualized as filling defects (arrows). LPO, left posterior oblique; RPO, right posterior oblique; B: Venous angiogram (left) shows site of tumor (infiltrative reticulum cell sarcoma) in inferior vena cava. Right ventricular cineangiogram (right) demonstrates large embolus from same tumor in right pulmonary artery.

and appears to relate to hemolysis-induced endothelial dysfunction and subsequent dysregulation of arginine metabolism and reduced NO bioavailability. Initial results of studies using sildenafil to treat chronic pulmonary hypertension appear promising (95). New studies suggest a potential benefit of nitrite therapy in this disorder (96).

PORTAL HYPERTENSION

Severe liver disease producing cirrhosis and intrahepatic portal hypertension, as well as portal vein thrombosis producing extrahepatic portal hypertension have been associated with the development of pulmonary hypertension (97). Severe structural changes, consisting of medial hypertrophy, occlusive cellular intimal hyperplasia, plexiform lesions, and dilation complexes occur in the peripheral pulmonary arteries. It has therefore been postulated that the “toxic liver” is unable to degrade a certain vasoconstrictor substance that then circulates through the lung in high concentration causing structural damage to the vessels. In some patients with liver disease, however, there is generalized vasodilation of the vessels in the lung (98). In other patients, anastomoses develop between pulmonary and hepatic arteries (99). Thus, the pulmonary vascular response (both structural and hemodynamic) in individual patients with liver disease may differ greatly. Severe pulmonary hypertension should not be considered a contraindication to

liver transplantation because regression of the hemodynamic abnormality has been described. Recently portopulmonary hypertension has been linked to a polymorphism in S100A4 (100), a gene we linked to experimental pulmonary hypertension discussed later in this chapter.

GRANULOMATOUS AND COLLAGEN VASCULAR DISEASES AND IMMUNE/INFECTIOUS DISEASES

Pulmonary hypertension may occur either in adults or in children with sarcoidosis. This seems to be due to the presence of obstructive granulomas within the pulmonary arteries. Pulmonary hypertension also may occur in association with collagen vascular disease, such as scleroderma, and the CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, telangiectasia) and more rarely in association with systemic lupus erythematosus, rheumatoid arthritis, Takayasu arteritis, polymyositis, and dermatomyositis. While the pathologic features of PAH include thromboemboli, particularly in association with the antiphospholipid syndrome (101) an immune/inflammatory vasculitis appears to be the initiating event. The prevailing hypothesis is that there is endothelial injury coupled to an immune defect and this leads to a peri- and intravascular inflammatory response that causes vascular lesions that lead to progressive PAH. In addition to high circulating levels of endothelin-1 (indicative of an endothelial injury), there is increased production of autoantibodies that reflect the immune compromise. Activating antibodies to platelet-derived growth factor (PDGF) receptor (102) could explain the proliferative response of SMCs causing vascular lesions. In an allergic model of PAH, an IL-13-mediated increase in a resistin-like molecule was observed and this protein can induce SMC proliferation (103).

The results of therapy, including intravenous prostacyclin, have not appreciably improved long-term survival in the subset of patients with PAH in association with systemic sclerosis. These patients appear to deteriorate with lower levels of pulmonary artery pressure and resistance, perhaps because of intrinsic abnormalities in the right ventricle or related to increased stiffness of the conduit pulmonary arteries (104).

Inflammation has been linked to the development of PAH, and both the chemokine receptor CX3CR1 and the chemokine fractalkine appear to be elevated (105). Severe PAH has been associated with acquired immunodeficiency syndrome, even in the absence of lung parenchymal disease (106), and has been reproduced experimentally (107). Moreover, the development of PAH in the subset of patients with human immunodeficiency virus (HIV) infection may be a function of the immunogenetic background (i.e., human leukocyte antigen class II alleles) (108). More recently, a link has been made between expression of human herpesvirus 8 associated with Kaposi sarcoma and idiopathic PAH (109), although this association has not been confirmed in all populations studied.

It appears that the Kaposi sarcoma virus can stimulate lysosomal-mediated degradation of BMPR2 (110), the receptor that is mutated and dysfunctional in patients with idiopathic pulmonary hypertension. This receptor normally protects the pulmonary vasculature, as is discussed later in the chapter. The HIV-nef gene has been implicated in plexogenic pulmonary vascular lesions associated with PAH in HIV-infected patients and Simian immunodeficiency virus-infected nonhuman primates (111).

Recently, we have reported that the mouse that overexpresses S100A4/Mts1 develops extensive and severe neointimal lesions following injection of the gamma murine herpes

Figure 66.16. Heightened neutrophil elastase expression in cultured pulmonary artery SMCs is localized to neointimal lesions in lungs from patients with idiopathic pulmonary artery hypertension (IPAH). **A:** Western immunoblots on top and relative densitometry on the bottom comparing neutrophil elastase relative to β -actin in cultured pulmonary artery SMCs isolated from three IPAH patients versus three unused donor lungs as controls. Bars represent mean of $n = 3$ per group, with $*p < 0.05$ determined by t -test. Representative immunohistochemistry from one of five IPAH and one of four control lungs. Cells strongly expressing neutrophil elastase are apparent in the subendothelium and media of pulmonary arteries with neointimal or plexiform lesions in the IPAH lung (B,D). Little immunoreactivity for neutrophil elastase was apparent in the pulmonary arteries in the control donor lung (F). Background immunoreactivity is apparent using IgG as a control (C,E). Arrowheads point to regions of intense immunoreactivity. Marked areas are shown with twofold higher magnification, on the right. Scale bars, 100 μ m (B–F). (From Kim YM, Haghighat L, Spiekerkoetter E, et al. Neutrophil elastase is produced by pulmonary artery smooth muscle cells and is linked to neointimal lesions. *Am J Pathol* 2011;179:1560–1572, with permission.)

virus-68 (the murine homologue of human herpesvirus-8). This is associated with an elevated elastase activity that we have now identified as neutrophil elastase produced by pulmonary artery SMCs. In this model, we identified high levels of neutrophil elastase in SMCs and also observed high levels of this enzyme in the vessels from patients with pulmonary hypertension (Fig. 66.16) (112).

The high incidence of PAH in areas of the world endemic for schistosomiasis has resulted in a number of experimental studies addressing pathogenesis and pathobiology of this complication. About 10% of patients with schistosomiasis will develop portal hypertension and 10% of those (1% total) will have PAH. Chronic infection with the high-dose cercariae resulted in extensive lung vascular remodeling and PAH (113) (Fig. 66.17).

Allergic responses to ovalbumin or to aspergillus (114) can result in extensive vascular remodeling although in this model of disease, as in the S100A4 overexpressing mice inoculated with virus, elevation in right ventricular systolic pressure is not observed. A Th2 immune response characterizes both the ovalbumin and the cercariae models but not the viral model of pulmonary vascular remodeling. In mice lacking prostaglandin synthase, induction of allergic inflammation with the house dust mite induces intense pulmonary vascular remodeling; changes that are reversed by administration of prostaglandin E2.

A recent study has shown that in the model of PAH in which loss of arteries is induced by the combination of injection of an inhibitor of VEGF and hypoxia, depletion of T cell subsets actually worsens the pathology (115). This adverse response has been attributed to unbalanced B cell activity resulting from impaired regulatory T cell (Treg) production (116).

In patients with idiopathic pulmonary artery hypertension (IPAH), there is a pronounced inflammatory response, heightened circulating levels of cytokines and their receptors, stromal-derived factor-1 and monocyte chemoattractant protein (MCP)-1, as well as fractalkine (105), and its cognate receptor, which are associated with heightened SMC proliferation. Also intriguing are recent studies suggesting that heightened expression of the transcription factor NFATc2 that is associated with inflammatory cells may underlie PAH. Increased nuclear NFATc2 is observed in T cells from IPAH patients and in pulmonary vascular lesions, and this can lead to repression of Kv 1.5 channel expression. NFATc2 can be inhibited by a small molecule and its nuclear translocation can be suppressed by cyclosporine. These agents can also attenuate experimentally induced PAH (117).

DRUGS AND TOXINS

Clinical Studies

The ingestion of substances associated with PAH include amphetamine, as well as the fenfluramine compounds, for example, dexfenfluramine, a serotonin antagonist (118). These agents resemble epinephrine in their chemical structure, suppress appetite, and cause symptoms of right-sided heart failure in 10% of patients within 6 to 12 months of initial administration. Microscopic changes in the lung are similar to those in patients with end-stage pulmonary vascular disease, regardless of etiology (i.e., medial hypertrophy and intimal fibroelastosis, including the presence of plexiform and dilation lesions).

Figure 66.17. Representative photomicrographs ($\times 100$ magnification) of lung sections. **A:** Mice infected with *Schistosoma mansoni* for 25 weeks with eggs in the lung; numerous grossly remodeled vessels can be seen (arrows indicate remodeled vessels). **B:** In mice infected with *S. mansoni* for 25 weeks and treated with praziquantel for the final 8 weeks, no grossly remodeled vessels can be seen. Sections were stained with hematoxylin and eosin. Bar represents 10 μm . (From Crosby A, Jones FM, Kolosionek E, et al. Praziquantel reverses pulmonary hypertension and vascular remodeling in murine schistosomiasis. *Am J Respir Crit Care Med* 2011;184:467–473, with permission.)

Pathophysiologic studies have also suggested that there are similarities to primary PAH in terms of monoclonal expansion of endothelial cell populations (119). As previously mentioned, our studies have linked serotonin to increased production and secretion of S100A4/Mts1, a gene associated with advanced clinical and experimental PAH (22,23).

The toxic oils, such as rapeseed oil, have been implicated in the development of malignant PAH (120). Ingestion of pyrrolizidine alkaloids, such as bush tea, causes hepatic veno-occlusive disease, and a similar compound, monocrotaline, when ingested by animals, causes severe pulmonary vascular disease (121).

Experimental Studies

Rats that ingest the toxin monocrotaline develop pulmonary arterial changes that can be correlated with hemodynamic evidence of progressive PAH with increased pulmonary vascular resistance (122–127). Initially, there is an increase in cardiac output associated with extension of muscle into peripheral arteries that are normally nonmuscular. After a few weeks, when there is an increase in pulmonary artery pressure, medial hypertrophy of normally muscular arteries is apparent. After 3 weeks, when an increase in pulmonary vascular resistance occurs secondary to both a further rise in pulmonary artery pressure and a drop in cardiac output, there is a reduction in the number of peripheral pulmonary arteries, and “ghost,” or disappearing, vessels can be seen.

Ultrastructural studies have shown injury to the vascular endothelium within several hours of monocrotaline

injection; inflammatory cells and edema are apparent after 1 week. Studies carried out in our laboratory comparing the response to monocrotaline in neonatal, infant, and adult rats suggested that, in the neonate, transient inflammation causes a severe decrease in alveolar number. The development of vascular changes is similar in the three groups. In the infant rat, however, the abnormalities regress between 2 and 4 weeks after injection, whereas in the adult animal, they progress (122). Our studies showed that increased elastase activity not only initiated but also contributed to the progression of the vascular changes. Similar to pulmonary hypertension secondary to chronic hypoxia, there is an early increase in enzymatic activity only 2 days after injection of the toxin, but there is also a further increase in elastase activity observed with malignant progression of the disease in adult rats. Furthermore, we demonstrated that elastase inhibitors are effective in reducing the pulmonary hypertension and vascular changes (125). We have also shown that elastase inhibitors can effectively reverse the pulmonary hypertension that results from monocrotaline toxicity with values similar to those in control animals that did not receive this toxin (128) (Figs. 66.18 and 66.19). Reversibility of disease was associated with coordinated apoptosis and caspase-mediated degradation of the excess extracellular matrix (129) with regeneration of normal endothelial channels and precapillary vessels.

Based upon subsequent knowledge that the effect of elastase was critical in maintaining survival signals through epidermal growth factor receptors (EGFRs) (130), we recently blocked EGFR (131). In these studies, we were able to show reversal of progressive PAH that was sustained even 1 month after cessation of treatment. More recently, the use of a PDGF receptor blocker to reverse PAH in this experimental model (132) has prompted a case report showing the successful use of imatinib in a patient with advanced pulmonary vascular disease (133). This report has prompted several clinical trials using imatinib in patients with PAH, with the published data suggesting potential efficacy in those with the most severe disease (134).

Others have used eNOS gene therapy in association with endothelial progenitor cell administration (Fig. 66.20) (135,136), gene therapy with survivin (137) (Fig. 66.21), angiopoietin-1 (138), inhibition of the SERT (139), adrenomedullin (140), and the rho kinase inhibitor, fasudil (141). Recently, gene replacement therapy with the Bmpr2 has shown similar efficacy to that seen in the hypoxia model (142). Potassium channel dysfunction is implicated in the pathogenesis of pulmonary vascular disease (143), and gene therapy restoring K channel function has been used effectively to suppress pulmonary vascular disease (67) but this has not been tested to reverse the process.

Recently, this group has shown abnormal metabolism linked to inflammation in pulmonary hypertension and important novel therapeutic targets linked to reversing a fatty acid oxidation defect (144). An important link between altered metabolism and inflammation underlies the propensity of mice (145,146) and highlights the role of mitochondrial dysfunction as pivotal to the pathology (147) (Fig. 66.22). Mice with insulin resistance develop pulmonary hypertension (148) and there is a high incidence of metabolic syndrome in women with idiopathic pulmonary hypertension (74). Mice with loss of peroxisome proliferator-activated receptor- γ (PPAR γ) in endothelial (149) or in SMCs (150) have spontaneous pulmonary hypertension and this can be rescued by adding back a apelin, a downstream target of PPAR γ gene regulation (151).

Other experimental models of chronic inflammation, such as repeated injections of endotoxin, and tumor necrosis factor also have been associated with the development of pulmonary vascular changes. In models of chronic air

Figure 66.18. Cellular mechanism responsible for reversal of pulmonary artery muscularity. Elastase inhibition arrests tenascin-C accumulation and proliferation and induces apoptosis and loss of extracellular matrix (such as elastin). A–P: Days refer to time after injection of monocrotaline: A,E,I,M, day 21; B,F,J,N, day 28; C,G,K,O, day 28; D,H,L,P, day 28. M–P: Proliferating vascular cells, shown by immunohistochemistry for proliferating cell nuclear antigen (PCNA); dark nuclei are PCNA-positive cells. Q,R: Percent of smooth muscle cells (SMCs) that are TUNEL positive (Q) or PCNA positive (R). S: Densitometric quantification of elastin I, inhibitor treated (IZ, ZD0892; IM M249314); TUNEL, in situ DNA nick end labeling; u, untreated; v, vehicle treated. Graphed data represent mean \pm standard error of the mean of $n = 4$; scale bars represent $5 \mu\text{m}$; *, $p < 0.05$, compared with †, $p < 0.05$, compared with results on day 21 in rats treated with monocrotaline. (Reproduced from Cowan KN, Heilbut A, Humpl T, et al. Complete reversal of fatal pulmonary hypertension in rats by a serine elastase inhibitor. *Nat Med* 200;6:698–702, with permission.)

Figure 66.19. We have speculated how a stimulus could induce activity of an elastolytic enzyme and how this might stimulate the remodeling process. The process of progressive pulmonary hypertension involves a series of switches in the smooth-muscle cell (SMC) phenotype (i.e., differentiation of muscle from nonmuscle precursor cells, SMC hypertrophy, proliferation accounting for medial hypertrophy, and SMC migration resulting in neo-intimal formation). In response to a stimulus, such as high flow and pressure, the first “casualty” is the endothelial cell. As a result of structural and functional alterations in endothelial cells, some of the barrier function would be lost, allowing a leak into the subendothelium of a serum factor normally excluded from this region. The serum factor could induce activity of an endogenous vascular elastase (EVE). This enzyme released from precursor or mature SMCs would activate growth factors normally stored in the extracellular matrix in an inactive form, such as basic fibroblast growth factor (bFGF) and transforming growth factor(TGF)- β , which are known to induce smooth muscle hypertrophy and proliferation and increases in connective tissue protein (e.g., collagen and elastin) synthesis. Growth factors also induce tenascin, a matrix glycoprotein that amplifies the proliferative response as described in the text. This results in the differentiation of precursor cells to mature smooth muscle related to the muscularization of normally nonmuscular small peripheral arteries. In the muscular arteries, the release of growth factors would result in hypertrophy of the vessel wall. Continued elastase activity would cause migration of SMCs in several ways. The elastin peptides or degradation products of elastin can stimulate fibronectin, a glycoprotein that is pivotal in altering SMC shape and switches them from the contractile to motile phenotype.

Figure 66.20. Representative confocal projection images of lung sections perfused with fluorescent microspheres (green) suspended in agarose (i.e., fluorescent microangiography) and immunostained for alpha smooth muscle actin (red). A: Normal filling of the microvasculature was observed in control rats (a), whereas rats treated with monocrotaline (MCT) showed a marked loss of microvascular perfusion and widespread precapillary occlusion 21 days (b) and 35 (d) days after MCT injection. In the prevention model, animals receiving endothelial-like progenitor cells (ELPCs) displayed improved microvascular perfusion and preserved continuity of the distal vasculature (c). In the reversal model, eNOS-transduced ELPCs dramatically improved the appearance of the pulmonary microvasculature (f), whereas progenitor cells alone resulted in more modest increases in perfusion and little noticeable reduction in arteriolar muscularization (e), calibration bars=100 μ m. In the prevention model, animals receiving ELPCs displayed improved microvascular perfusion (B) and preserved continuity of the distal vasculature (C), and similar findings were observed in the reversal model. NM, nonmuscular; PM, partially muscular; FM, fully muscular. (Reproduced from Zhao YD, Courtman DW, Deng Y, et al. Rescue of monocrotaline-induced pulmonary arterial hypertension using bone marrow-derived endothelial-like progenitor cells: efficacy of combined cell and eNOS gene therapy in established disease. *Circ Res* 2005;96:442–450, with permission.)

Figure 66.21. Gene therapy of rat monocrotaline-pulmonary artery hypertension (MCT-PAH) with adenovirus-green fluorescent protein survivin-mutant (Ad-GFP-S-M) improves hemodynamics, reduces remodeling of the pulmonary artery (PA) resistance, and prolongs survival. **A:** Representative high-fidelity PA pressure tracings and mean data show that Ad-GFP-S-M, but not Ad-GFP, therapy reduces PA pressure and pulmonary vascular resistance index (PVRi), without altering systemic hemodynamics. SVRi, systemic vascular resistance index. **B,C:** Ad-GFP-S-M, but not Ad-GFP, reduces right ventricle (RV) thickness measured in parasternal short axis and preserves the normal round shape of the left ventricle (LV). Similarly, Ad-GFP-S-M reduces pulmonary artery acceleration time (PAAT). Resistance PA remodeling, as measured by percent medial thickness, is reduced by treatment with Ad-GFP-S-M. RVOT, RV outflow tract; AV, aortic valve; PV, pulmonary valve. Magnification in (C), ×40. **D:** Targeting survivin with inhaled gene therapy in MCT-PAH significantly prolongs survival within the study period. * $p < 0.05$ versus MCT; † $p < 0.05$ versus Ad-GFP. (Reproduced from McMurtry MS, Archer SL, Altieri DC, et al. Gene therapy targeting survivin selectively induces pulmonary vascular apoptosis and reverses pulmonary arterial hypertension. *J Clin Invest* 2005;115:1479–1491, with permission.)

embolization and thoracic irradiation, in which pulmonary hypertension and vascular changes are produced, endothelial injury is the common observation, as it is in the monocrotaline model.

IDIOPATHIC PULMONARY HYPERTENSION

After all known causes of pulmonary hypertension have been ruled out, the diagnosis becomes that of idiopathic pulmonary hypertension. This unexplained disease, in which a structural abnormality is always found either in the arteries or in the veins, occurs both in children and adults and sometimes with a familial tendency (152–154). By the time the patient becomes symptomatic, the disease is usually advanced; in the absence of treatment, it is usually rapidly progressive and invariably fatal, although rare cases of spontaneous regression have been reported. The preponderance of affected females ranges in

some studies from a ratio of 4:1 to 2:1. In general, there is an inverse relationship between the age of onset of symptoms and the duration of illness until death. Children are most frequently diagnosed in infancy and in the absence of treatment may die within a year.

Recent attention has been directed to the genetics of this disease. Studies by Loyd et al. (155) have shown that there is genetic anticipation with the disease occurring earlier in subsequent generations and a preponderance of affected females at birth, suggesting that in the male there may be fetal wastage. In young children, the pathobiology suggests failure of the neonatal vasculature to open and a striking reduction in arterial number (156). In older children, intimal hyperplasia and occlusive changes are found in the pulmonary arteries as well as plexiform lesions. In adults, in addition to the latter changes, “ghost” arteries also have been reported. An electron microscopic study (157), performed on a lung biopsy of an adult patient, showed severe endothelial injury, which was speculated to be the initial

Figure 66.22. Metabolic hypothesis of pulmonary arterial hypertension (PAH). PAH pulmonary artery SMC mitochondria have decreased pyruvate influx, hyperpolarized mitochondria and reduced Krebs cycle activity, and mitochondrial-reactive oxygen species (ROS) (free radical) production. Hyperpolarized mitochondria and suppressed mROS close the mitochondrial transport pore (MTP), “trapping” cytochrome c, and apoptosis-inducing factor (AIF) in the matrix, resulting in resistance to apoptosis. This also results in closure of redox-sensitive Kv channels and influx of intracellular Ca^{2+} resulting in contraction and proliferation. Increased Ca^{2+} activates transcription factors (HIF and NFAT) that further suppress apoptosis and potentiate proliferative response. This whole mechanism initiated by hyperpolarization of mitochondria can be reversed by the inhibition of pyruvate dehydrogenase kinase (PDK), by dichloroacetate (DCA) thereby activating pyruvate dehydrogenase (PDH). In addition, inhibition of fatty acid oxidation (FAO) indirectly activates PDH (via the Randle cycle), thus mimicking DCA, also reversing PAH. *Denotes potential additional targets for therapy predicted by this mitochondria-centric model of PAH pathogenesis. (From Dromparis P, Sutendra G, Michelakis ED. The role of mitochondria in pulmonary vascular remodeling. *J Mol Med (Berl)* 2010;88:1003–1010, with permission.)

site of damage. In some patients, defective vWF (158) and fibrinolysis (159) have been described. Additional features include thickening of the pulmonary adventitia and venous hypertrophy as well as endothelial cell hyperplasia (160). Immunohistochemical changes include increased expression of TGF- β , matrix proteins, and macrophages (161), as well as the molecules observed with advanced lesions in congenital heart defect patients, that is, fibronectin, tenascin C, and S100A4/Mts1.

In the venous form of unexplained pulmonary hypertension, the clinical presentation is somewhat different from the arterial in that orthopnea is a characteristic feature and changes suggesting pulmonary edema are apparent on the chest radiograph, despite a normal pulmonary wedge pressure. Structural abnormalities in the lung are most striking in both large and small veins and consist of loose, fibrous intimal hyperplasia

with dilated lymphatics. There is also evidence that pulmonary venous occlusive disease might occur in utero. A number of factors affect the prognosis in idiopathic pulmonary hypertension such as insulin resistance in female patients (74) and iron deficiency associated with elevated hepcidin levels (162) (Fig. 66.23).

A mutation in the gene for *Bmpr2* is associated with 60% of familial cases of PAH (152–154), but the penetrance is only about 20%. That is, 80% of family members who carry the mutation will never develop PAH. Moreover, mutations in *Bmpr2* have been described in 20% of sporadic cases of PAH (163,164). In addition, other BMP-TGF beta receptor family members such as ALK1 and endoglin that were first identified as mutated in hemorrhagic telangiectasia are also occasionally mutated in patients with PAH (165,166). Focusing additional evidence on this family of receptors, a microsatellite instability

Figure 66.23. Serum transferrin receptor levels and idiopathic pulmonary arterial hypertension (IPAH). **A:** Distribution of soluble transferrin receptor (sTfR) levels according to World Health Organization (WHO) functional class in patients with IPAH and in healthy controls. *p* value relates to Kruskal-Wallis ANOVA. **B:** Kaplan-Meier survival estimates stratified by sTfR level below (blue solid line) or above (green dashed line) the predefined upper limit of the normal range, 28.1 nmol/L. (From Rhodes CJ, Howard LS, Busbridge M, et al. Iron deficiency and raised hepcidin in idiopathic pulmonary arterial hypertension: clinical prevalence, outcomes, and mechanistic insights. *J Am Coll Cardiol* 2011;58:300–309, with premission.)

in the TGF- β receptor II, resulting in its reduced expression and function, is observed in patients with IPAH (167). Recent studies have linked the penetrance of pulmonary hypertension in affected family members to the expression of *Bmpr2* from the normal allele (168). A host of new studies also implicate estrogen metabolism (169) and estrogen receptor expression (170) to the female predisposition to pulmonary hypertension. Although the penetrance is low, the functional link between mutations in *Bmpr2* and PAH is reinforced by the fact that independent of a mutation in *Bmpr2*, IPAH patients have reduced *Bmpr2* protein expression as do, to some extent, patients with secondary PAH. The functional consequence of reduced or absent *Bmpr2* in endothelial or SMCs is related to the pathologic features observed in PAH and discussed below. Impaired downstream signaling has been described in association with a variety of *Bmpr2* mutations (171,172), and there is also a newly described mutation in pSmad 8 in a patient with IPAH. A few studies have specifically addressed the transcription factors and genes that are subsequently upregulated or suppressed as a result of impaired *Bmpr2* signaling. We have shown in SMCs that BMPs can induce PPAR γ transcriptional activity to induce apoE, a suppressor of SMC proliferation (150). These studies showed that the main function of *Bmpr2* signaling is to suppress the proliferative response of SMCs when there is stimulation by growth factors that are induced under conditions of vascular injury. In endothelial cells, in contrast to SMCs, BMPs induce a complex between PPAR γ and β -catenin to regulate genes like apelin that have important protective paracrine and autocrine effects (151). BMPs suppress apoptosis of endothelial cells in response to injury and are proangiogenic, indicating that they may play an important role in repairing damaged microvessels. Apelin, in addition to being a factor that improves endothelial survival, can also suppress SMC proliferation, vasodilate, and improve cardiac function (173). Interactions between the *Bmpr2* signaling pathway and the Notch signaling pathway led investigators to determine that

This is a summary schema that outlines processes that are current and future targets of therapy. Those with asterisk are in trial for PAH, those in green are in trial for other indications, and those in blue are in clinical use for other indications. Modified from Robinovitch M. Molecular pathogenesis of pulmonary arterial hypertension. *J Clin Invest* 2008;118:2372–2379.

Figure 66.24. Schema outlining factors that converge in the molecular pathogenesis of PAH and how these may interact with *Bmpr2* dysfunction, a known genetic defect associated with PAH. This schema focuses on factors causing increased SMC and fibroblast proliferation as well as apoptosis of endothelial cells, causing an initial reduction in vessel number, followed by proliferation of apoptosis-resistant endothelial cells (ECs) in plexiform lesions. It shows multiple levels of interaction, with numerous factors related as described in the text. For example, serotonin stimulates both PDGF-mediated and S100A4/Mts1-mediated SMC and fibroblast proliferation and it also reduces Kv channel function, as does hyperpolarized mitochondria. *Bmpr2* dysfunction causes Kv channel dysfunction and enhances transient receptor potential Ca^{2+} (TRP) channel activity, which increases intracellular calcium levels, and may (as reflected by question mark) induce elastase activity. Viruses of the herpes family can induce elastase activity. Elastase, via activation of matrix metalloproteinases (MMPs) and tenascin C (TN-C), upregulates growth factor (GF) receptors such as epidermal GF receptors (EGFRs) and also triggers release of growth factors such as EGF from the extracellular matrix, all of which leads to SMC proliferation. *Bmpr2* dysfunction can also increase the mitogenic activity of PDGF activity, increase SMC proliferation by suppressing peroxisome proliferator-activated receptor (PPAR) γ , and increase transforming growth factor (TGF)- β activity. *Bmpr2* dysfunction can enhance inflammation via osteoprotegerin and interleukin (IL)-6. The transcription factor, nuclear factor of activated T cells (NFAT)c2 can suppress Kv channel function. Other inflammatory mediators such as fractalkine and mast cell proteinase (MCP)-1 can, in addition to osteoprotegerin and IL-6, increase SMC proliferation. *Bmpr2* dysfunction can lead to EC apoptosis, as can elastase activity. EC apoptosis may predispose to the development of apoptosis-resistant ECs in plexiform lesions. Loss of *Bmpr2* also activates Notch signaling that induces SMC proliferation. (Modified from Rabinovitch M. Molecular pathogenesis of pulmonary arterial hypertension. *J Clin Invest* 2008;118:2372–2379.)

in PAH there is an increase in activity of Notch. The cleavage of Notch following its interaction with a receptor on the SMC surface leads to the internalization of the Notch intracellular domain that serves as a transcription factor to induce genes that cause SMC proliferation (174). Blockade of gamma secretase, the enzyme that cleaves Notch, resulted in prevention and regression of experimental PAH.

SUMMARY

The experimental studies point to intersecting and highly interrelated pathways that underlie the pathobiology of pulmonary hypertension (Fig. 66.24). They suggest potential new therapies, some of which are already finding their way into clinical practice, as delineated in Table 66.6.

FUTURE DIRECTIONS

Further insights into the pathophysiology of PAH will come from genomic studies in which extensive sequencing will likely

reveal additional genetic variants associated with this disease. Epigenetic studies are currently being undertaken to address whether changes in chromatin remodeling will help explain why the lung is a target organ and how environmental factors perturb the genome and can lead to further alterations in expression of a rare variant or in the genes that interact with this rare variant. A number of studies using experimental models of pulmonary hypertension point to compelling changes in methylation (175) that silence genes such as eNOS (176) or superoxide dismutase (64) or that confer a proinflammatory signature on fibroblasts (177) from patients with pulmonary hypertension. Regulation of *Bmpr2* signaling also can be under epigenetic control (63).

High throughput gene expression and proteomic studies are also revealing changes that reflect specific pathways that are perturbed and how environmental exposures and immune defects can interact with a vulnerable vasculature. Intense focus on aberrations in immune mechanisms ranging from disturbances in T cell subsets to autoantibody production will be important in understanding all forms of PAH. The more we learn about specific pathways, the better equipped we will be to develop new treatments for pulmonary hypertension.

Clinical Management of Pediatric Pulmonary Arterial Hypertension

D. Dunbar Ivy

Pulmonary hypertension (PH) is an important cause of morbidity and mortality in pediatric patients (1,2). PH is defined as an elevation of pulmonary artery pressure (PAP) due to any cause. Pulmonary arterial hypertension (PAH) is defined as a specific type of PH caused by pulmonary vascular disease of the precapillary arterioles in the absence of other causes. Advances in understanding the pathobiology of PAH have led to novel therapies; however, there remains no cure for some forms of PAH, such as idiopathic pulmonary arterial hypertension (IPAH) (3). Evaluation and treatment for known causes of PH is crucial as the best strategy for treatment includes treatment of any underlying disorders. The selection of appropriate therapies for PH is complex and must be carefully done according to the etiology and determination of pulmonary vasoreactivity at cardiac catheterization.

DIAGNOSIS AND CLASSIFICATION

PH is no longer classified as primary or secondary. Currently, diseases are grouped according to similar pathology, pathophysiology, and treatment. A revision of the World Health Organization (WHO) classification, including most of the forms of PH encountered in children, was proposed at the WHO Dana Point meeting in 2008 (Table 67.1) (4); however, this classification was not designed specifically for children. Group 1 is defined as PAH. This form of PH is due to pulmonary vascular disease of the precapillary arterioles in the absence of other causes (such as left heart disease—Group 2). PAH is defined as a mean PAP ≥ 25 mm Hg at rest, with a normal pulmonary capillary wedge pressure (≤ 15 mm Hg) and increased pulmonary vascular resistance (PVR) index (≥ 3 Wood units \times m²) (4). A recent article reviews the clinical presentation of children with PH and outlines the difficulties of classifying pediatric PH according to this classification (5). In particular, the adult classification does not include abnormalities of alveolar growth and development nor does it account for many of the syndromes seen in pediatric practice, such as Down syndrome. Patients with PAH and congenital heart disease (CHD) are a heterogeneous population, with a range of vascular disease: some patients have a right-to-left central shunt (Eisenmenger syndrome), others have a residual shunt and severe PAH but are not cyanotic, some patients with a small shunt may have severe PAH and are more similar to IPAH, and finally it is well known that PAH may persist and progress despite corrective cardiac surgery (Table 67.2) (4). PAH may be idiopathic (IPAH) or heritable (HPAH) with no underlying cause, or associated with a specific disease (associated PAH). Mutations of the bone morphogenetic protein receptor, type 2 (BMPR2) gene are the most common genetic abnormalities known to cause HPAH. Most studies in children have focused on PAH associated with CHD (Table 67.3) and IPAH (6–8). IPAH is a diagnosis of exclusion and thus

is defined as PAH unexplained by other causes. An extensive evaluation to rule out secondary causes must be performed before a patient can be diagnosed with IPAH. Persistent pulmonary hypertension of the newborn (PPHN) is the most common cause of PH in the neonatal period, and is most often reversible. PH associated with left heart disease is defined as Group 2 PH. In these disorders, the main cause of PH is an elevation of left heart pressure due to impaired relaxation (diastolic dysfunction) or an anatomic lesion that leads to high left atrial pressure (such as mitral stenosis). Group 3 PH, or PH associated with lung disease or hypoxemia, is separated from Group 1 as treatment of the lung disorder may result in normalization of PAP. PH associated with chronic lung diseases, such as bronchopulmonary dysplasia (BPD) or congenital diaphragmatic hernia (CDH) is increasingly recognized as an important cause of PH in the infant and child. Group 4 PH, or PH associated with chronic thromboembolic disease, is a rare cause of PH in children, but is still important to recognize and treat as therapy may be curative. Group 5 consists of miscellaneous disorders that do not fit well into Groups 1 to 4.

Due to the difficulties of applying the Dana Point Classification to children, a working group of the Pulmonary Vascular Research Institute developed a unique pediatric classification (Table 67.4) (9). This classification recognizes the concepts of perinatal maladaptation, maldevelopment, and pulmonary hypoplasia as important contributors to pediatric PH disease. This classification is not meant to be a guide for therapy. Many children presenting with PH have complex heterogeneous disease consisting of prematurity, a chromosomal or genetic anomaly, a congenital cardiac defect, chronic aspiration, and sleep-disordered breathing. In this classification, PH in children is defined as in adults for a biventricular circulation, but PH in the setting of single ventricle physiology is defined as a PVR index >3.0 Wood units \times m² or a transpulmonary gradient (TPG) >6 mm Hg (9).

CLINICAL PRESENTATION

Symptoms of PH in children are frequently misleading and the diagnosis may be unrecognized for some time. A high degree of suspicion should be the rule and PH should be suspected in any child with undue shortness of breath, tiredness, or a syncopal episode. In patients with asthma who do not respond appropriately to medical therapy, PH should be considered in the differential diagnosis. Other clinical symptoms may include seizures, hemoptysis, chest pain, dizziness, syncope, arrhythmias, or in advanced disease, symptoms of right heart failure, for example, facial edema. For IPAH patients or those with CHD who have undergone complete surgical repair with elevated PVR, syncope or hypoxic seizures can occur. Thus, children are sometimes misdiagnosed with a seizure disorder prior to making the diagnosis of PH. In contrast, syncope is a rare presenting symptom in patients with Eisenmenger syndrome.

TABLE 67.1

Updated WHO Clinical Classification of Pulmonary Hypertension (Dana Point, 2008)

1 Pulmonary arterial hypertension

- 1.1 Idiopathic
- 1.2 Heritable
 - 1.2.1 *BMPR2*
 - 1.2.2 *ALK1*, endoglin (with or without hereditary hemorrhagic telangiectasia)
 - 1.2.3 Unknown
- 1.3 Drug- and toxin-induced
- 1.4 Associated with (APAH)
 - 1.4.1 Connective tissue diseases
 - 1.4.2 HIV infection
 - 1.4.3 Portal hypertension
 - 1.4.4 Congenital heart disease
 - 1.4.5 Schistosomiasis
 - 1.4.6 Chronic hemolytic anemia
- 1.5 Persistent PH of the newborn

1' PVOD and/or PCH

2 PH due to left heart disease

- 2.1 Systolic dysfunction
- 2.2 Diastolic dysfunction
- 2.3 Valvular disease

3 PH due to lung diseases and/or hypoxemia

- 3.1 Chronic obstructive pulmonary disease
- 3.2 Interstitial lung disease
- 3.3 Other pulmonary diseases with mixed restrictive and obstructive pattern
- 3.4 Sleep-disordered breathing
- 3.5 Alveolar hypoventilation disorders
- 3.6 Chronic exposure to high altitudes
- 3.7 Developmental abnormalities

4 Chronic thromboembolic PH

5 PH with unclear and/or multifactorial mechanisms

- 5.1 Hematologic disorders: myeloproliferative disorders, splenectomy
- 5.2 Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, vasculitis
- 5.3 Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
- 5.4 Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

TABLE 67.2

Clinical Classification of Congenital Systemic-to-Pulmonary Shunts associated with Pulmonary arterial Hypertension

■ Eisenmenger syndrome

Includes all systemic-to-pulmonary shunts due to large defects, leading to a severe increase of PVR and resulting in a reversed (pulmonary-to-systemic) or bidirectional shunt. Cyanosis, erythrocytosis, and multiple organs involvement are present.

■ PAH associated with systemic-to-pulmonary shunts

In these patients with moderate-to-large septal defects the increase of PVR is mild to moderate, systemic-to-pulmonary shunt is still largely prevalent and no cyanosis is present at rest.

■ PAH with small septal defects

In these cases with small defects (usually VSDs <1 cm and ASD <2 cm of effective diameter assessed by echo) the clinical picture is very similar to idiopathic PAH.

■ PAH after corrective cardiac surgery

In these cases, CHD has been corrected but PAH either is still present immediately after surgery or has recurred several months or years after surgery in the absence of significant immediate postoperative residual lesions.

Reprinted from Simonneau G, Robbins IM, Beghetti M, et al. Updated clinical classification of pulmonary hypertension. *J Am Coll Cardiol* 2009;54:S43–S54, with permission from Elsevier.

SIGNS AND SYMPTOMS

The physical signs of PAH include a single and loud P2 without respiratory variation, right ventricular lift, and hepatomegaly with peripheral edema in the case of heart failure. In cases of severe disease, the P2 may be palpable. A diastolic murmur of pulmonary insufficiency, a holosystolic murmur of tricuspid regurgitation, or gallop rhythm may be audible. In infants, symptoms are less specific and may involve poor appetite, failure to thrive, lethargy, diaphoresis, tachypnea, tachycardia, and irritability (10–12).

EVALUATION

Because of the many diseases associated with PH, a methodical and comprehensive evaluation is important. The most successful strategy in treatment of PH is the correction of an underlying abnormality, rather than addition of vasodilator therapy. A diagnostic algorithm is shown in Figure 67.1 (13). Special situations may predispose to the development of PAH. As an example, children living at high altitude and presenting with high-altitude pulmonary edema (HAPE) should be screened for PH (14). In addition, children with biliary atresia, cavernous transformation of the portal vein, primary sclerosing cholangitis, or cryptogenic cirrhosis, may have portopulmonary hypertension (PPHTN) with an associated high mortality (15,16).

CHEST RADIOGRAPHY

The enlargement of the central pulmonary artery and/or right ventricle (RV) on chest radiography suggests the presence of

PAH. Prominence of the main pulmonary arteries is apparent in most patients with IPAH. The chest radiograph may show variable peripheral lung fields, depending on the amount of pulmonary blood flow. As pulmonary blood flow decreases as a result of increasing PVR, the lung fields become progressively oligemic. Chest radiography findings may be useful to uncover secondary causes of PH: pulmonary venous congestion may suggest pulmonary veno-occlusive disease (PVOD) or pulmonary capillary hemangiomatosis (PCH), hyperinflation or kyphosis are signs of restrictive lung disease, and asymmetry of the enlarged central pulmonary arteries may

warrant investigation of chronic thromboembolic disease or PPHTN (12,17,18). Asymmetric lung volumes may suggest either pulmonary arterial or pulmonary venous abnormalities. A unilateral small lung may be seen in unilateral “absence” of a pulmonary artery, scimitar syndrome, or unilateral congenital absence of pulmonary veins.

ELECTROCARDIOGRAPHY

Electrocardiography (ECG) is often the first test to suggest PH by showing RV hypertrophy and right atrial enlargement. Evidence of RV hypertrophy on ECG is present in most but not all children with PH. ECG findings include a qR complex in lead V1 or V3R regardless of voltage. An upright T wave in V1 is indicative of RV hypertrophy from 7 days to 7 years. However, some studies have suggested that the specificity (69%) and positive predictive value (67%) of EKG is low in children with an echocardiographic diagnosis of PH (19). However, the sensitivity is likely higher, especially in combination with a complete physical examination.

ECHOCARDIOGRAPHY

Echocardiography is the most useful noninvasive screening tool to evaluate patients with a clinical suspicion of PAH, and can diagnose almost all congenital heart disease. (20,21). The echocardiogram documents RV size and function, left ventricular systolic and diastolic function, morphology and function of valves, and the presence of pericardial effusion or a patent foramen ovale. Doppler ultrasound can be used noninvasively to estimate the pulmonary artery systolic pressure (PASP). PASP can be determined by measuring the peak systolic pressure gradient from the RV to the right atrium and calculated using the Bernoulli equation ($4v^2$, where v is the maximum velocity of the TR jet measured by continuous wave Doppler and added to the estimated right atrial pressure)

(Fig. 67.2). One must be aware that using the tricuspid regurgitant jet velocity as an estimate of PASP can over or underestimate the PAP and thus other features of the echocardiogram are essential to support the diagnosis of PH (22). A qualitative assessment of RV function is also important. This is often challenging due to the geometry of the RV, which is more complex to analyze than the left ventricle. Several measures are available to attempt to quantify the degree of RV dysfunction including the Tei index, (myocardial performance index), RV ejection fraction, RV fractional area change, and the tricuspid annular plane systolic excursion (TAPSE) (23–29). Normal values for TAPSE in children have recently been published and should serve as a reference for children with PH (26). Pulmonic valve insufficiency is frequently seen, and characteristics of the pulmonic regurgitant flow velocity or changes in the systolic flow velocity profile across the pulmonic valve also can be used to estimate noninvasively the pulmonary artery diastolic pressure and the mean PAP (30). The presence of a pericardial effusion is rare in children, but when present, suggests a poor prognosis (27,31). As PH progresses and RV function worsens, the systolic portion of the cardiac cycle lengthens leading to an increase in the systolic:diastolic (S:D) ratio. The S:D ratio is higher in PH patients than in controls (1.38 ± 0.61 vs. 0.72 ± 0.16 , $p < 0.001$), and is associated with worse echocardiographic RV fractional area change, worse catheterization hemodynamics, shorter 6-minute walk distance (6MWD), and worse clinical outcomes independent of PVR or pressures (32).

Recent interest has grown in the area of measurement of total RV afterload by measurement of input vascular impedance. Impedance incorporates the sum of total compliance and resistance of the vascular bed (33–36). Currently, measurement

of impedance requires invasive pressure measurements in addition to measurement of Doppler flow. A recent manuscript on adults with PH showed that a measure of capacitance (stroke volume / pulse pressure) was a better predictor of survival than measurement of PVR (37,38). In children, pulmonary vascular input impedance has recently been shown to be feasible and predict clinical outcomes better than PVR in children with PAH (39).

CARDIAC MAGNETIC RESONANCE IMAGING

Cardiac magnetic resonance imaging (MRI) provides exact measurements of heart function and blood flow and is used with increasing frequency to evaluate patients with PAH (40–46). Cardiac MRI provides valuable information without radiation on RV volumes, mass, left ventricular septal bowing, cardiac index, and the presence of delayed contrast enhancement. Most young children require anesthesia for this procedure, which is an important consideration.

EXERCISE CAPACITY

Cardiopulmonary exercise testing (CPET) using cycle ergometry or 6-minute walk testing has been shown to correlate with disease severity and prognosis, and is helpful in assessing responses to clinical treatments. Recently published data showed that children can safely undergo CPET and the peak

Figure 67.1. Pediatric PAH diagnostic workup algorithm. *If unable to obtain a reliable test in a young child and there is a high index of suspicion for underlying lung disease, the patient may require further lung imaging, such as high resolution CT scan. **Children older than 7 years of age can usually perform reliably to assess exercise tolerance and capacity in conjunction with diagnostic workup. Pulmonary arterial hypertension in children: Diagnostic work up and challenges. *Prog Pediat Cardiol* 2009;27:7–11, with permission from Elsevier.)

Figure 67.2. Echocardiographic evaluation of PH. Spectral Doppler images of TR, demonstrating an optimal Doppler envelope to obtain the maximal TR velocity (top image), and of pulmonary insufficiency (bottom image). The left marker represents the peak early diastolic velocity and the right marker represents the end diastolic velocity of the pulmonary insufficiency Doppler curve. The arrow represents the end-diastolic “shoulder” of the pulmonary insufficiency jet. V(TR) max, tricuspid regurgitation peak velocity; V(PR) max, pulmonary insufficiency peak velocity; v(PR) min, pulmonary insufficiency end-diastolic velocity. (From Tissot C, Ivy DD. Echocardiographic evaluation of pulmonary hypertension. In: Beghetti M, ed. *Pediatric Pulmonary Hypertension*. Munich, Germany: Elsevier Urban & Fischer; 2011, with permission.)

oxygen consumption is strongly correlated to disease severity (47–49). A recent study of maximal CPET using cycle ergometry in children with PH concluded that the study could be performed safely in pediatric patients with PH, with the exception of patients with severe limitation who were excluded from exercise testing. ST-segment depression was graded as mild (19%) or moderate (1.5%). There were no significant adverse events, such as syncope, chest pain, or dizziness, and the study was stopped for fatigue in 53% of patients, leg fatigue in 23%, dyspnea in 21%, and miscellaneous reasons in 3% (49).

Six-minute walk test (6MWT) is a submaximal test shown to have a strong independent association with mortality among adults with IPAH (50–55); however, children often have less right heart failure for a given elevation of PAP leading to a further distance walked. A recent study compared CPET with 6MWT. Peak oxygen consumption and oxygen consumption at anaerobic threshold showed correlation with 6MWT distance ($r = 0.49$; $p = 0.001$ and $r = 0.40$, $p = 0.01$, respectively), while an inverse correlation was found between measures of ventilatory efficiency (VE/VCO_2) at anaerobic threshold and 6MWT distance ($r = -0.43$; $p = 0.005$). The 6MWT reflected maximal exercise capacity in children with a 6MWT distance below

300 m, but correlation was poor above 300 m (54). Normal values for 6MWD for children have recently been published (51–53,55) (Fig. 67.3).

CARDIAC CATHETERIZATION

PAH must be confirmed by catheterization, and acute pulmonary vasoreactivity testing should be performed to determine appropriate therapy. It is uncertain if the same definition of vasoreactivity should be applied for adults and children (see Therapy section). An anesthesiologist experienced in the management of PH should be present during the cardiac catheterization, as sedation may pose a significant risk to the patient with PAH. A skilled specialist with experience doing cardiac catheterizations on children with PAH should perform the procedure. Patients with suprasystemic PH pose particular risk (56,57). During the catheterization, baseline measures including right atrial pressure, PAP, systemic arterial pressure, mixed venous and systemic arterial saturation, cardiac index, pulmonary capillary wedge pressure, PVR, systemic vascular resistance (SVR), and PVR/SVR ratio should be obtained in addition to evaluation of shunts when there is a suspicion of

Data are shown as histograms and box-and-whiskers plots illustrating the median, 25th and 75th percentile as well as 5th and 95th percentile. (From Lammers AE, Hislop AA, Flynn Y, et al. The 6-minute walk test: normal values for children of 4–11 years of age. *Arch Dis Child* 2008;93:464–468, with permission.)

6MWD, six-minute walk distance

a systemic-to-pulmonary communication (58). Measurements must be obtained when the patient is closest to his/her usual hemodynamic and metabolic state and with a normal pH. Particular care is necessary at the time of catheterization to exclude additional intracardiac as well as extracardiac defects and to measure left ventricular filling pressure accurately to rule out postcapillary PH. Acute vasodilator testing is essential at the baseline diagnostic catheterization to assist in determining the optimal therapeutic regimen, and is described in a subsequent section.

LABORATORY ASSESSMENT

A comprehensive serologic evaluation looking for other systemic conditions that might lead to PAH and warrant additional treatment is performed (Table 67.5). Approximately, 5% to 20% of children with idiopathic disease may have an elevation of antinuclear antibodies as well as evidence of hypothyroidism or hyperthyroidism suggesting an autoimmune association (59–62). Furthermore, children should be screened for evidence of a hypercoagulable state as some may have an underlying coagulopathy such as antiphospholipid antibody syndrome or a lupus anticoagulant. The evaluation should include a liver ultrasound in cases suspected of having portopulmonary hypertension. A chest CT scan is important in the evaluation of the child with suspected IPAH to be certain that there is no underlying interstitial lung disease. CT scan of the chest may also be very helpful in evaluation for pulmonary capillary hemangiomatosis or veno-occlusive disease. HIV and sickle cell testing should be routinely performed in those patients at risk. If there is a family history of PH or early/sudden death, one could offer genetic testing for a BMPR2 mutation as well.

VENTILATION–PERFUSION SCINTIGRAPHY

Ventilation–perfusion lung scanning is mandatory in patients in whom IPAH is suspected to exclude chronic thromboembolic disease as a cause of the elevated PAP. Although thromboembolic disease is rare in children, it is one of the few diseases that can be cured with appropriate therapy including pulmonary

thromboendarterectomy. A normal or low-probability lung scan essentially rules out thromboembolic disease as the cause of the PH. Patients with IPAH will frequently have a patchy appearance to the perfusion scan.

PULMONARY FUNCTION TESTING/NOCTURNAL OXIMETRY

Evaluation for obstructive or restrictive lung disease should be performed as part of the evaluation of children with PH. Abnormalities of pulmonary function may be present in PAH patients particularly in the more advanced stages of the disease. A mild restrictive lung defect is seen in 20% to 50% of patients with IPAH. The presence of moderate or severe restrictive or obstructive physiologic defects should suggest another diagnosis. Mild reduction in the diffusion capacity is seen in most patients with IPAH. Severe hypoxemia is not usually present unless there is either intracardiac shunting via a patent foramen ovale or an open congenital heart defect in patients with Eisenmenger syndrome or severely depressed cardiac output with resultant mixed venous hypoxemia in both conditions. Nocturnal oximetry should be performed as a screening test for obstructive sleep apnea (OSA) or sleep-disordered breathing if there is a suspicion of OSA, for example, in a child with enlarged tonsils or adenoids and history of snoring. Sleep-disordered breathing may cause mild PH, which may resolve with nighttime continuous positive airway pressure.

EVALUATION OF REFLUX AND ASPIRATION

In the young child, reflux and aspiration may worsen PH. Many children with genetic syndromes, and in particular Down syndrome, routinely have aspiration. Silent aspiration is of particular concern, as these children do not always cough during aspiration events. Modified barium swallow study and measurement of reflux with a pH probe are important studies in the evaluation of these patients. In general, treatment of reflux and aspiration should precede treatment with pulmonary vasodilators.

BIOMARKERS

Interest in biomarkers has grown in the last several years. In adults, b-type natriuretic peptide (BNP) is a useful tool to assess mortality risk, progression of the disease, and response to therapy (63). Recent studies in children have begun to identify usefulness of BNP or N-terminal pro BNP (NT-proBNP) (64–66). BNP correlates positively with functional status in children with PAH, and values above 130 pg/mL are associated with increased risk of death or need for transplantation (65). Furthermore, change in BNP measurements over time correlates with the change in the hemodynamic and echocardiographic parameters of children with PAH, with a BNP value >180 pg/mL predicting a decreased survival rate in a more recent study (Fig. 67.4). The change in BNP level in a specific patient over time was shown to be more helpful in determining risk or

hemodynamic response to therapy than the average BNP value in a pediatric PAH population (64). NT-proBNP, uric acid, or norepinephrine levels have also been shown to correlate with outcome in children with PAH (66). When using a cutoff value of NT-proBNP of 1,664 pg/mL, sensitivity and specificity for predicting mortality was 100% and 94%, respectively (66).

LUNG BIOPSY AND WEDGE ANGIOGRAPHY

Lung biopsy is not used as part of the routine workup of PH given the relatively high risk of the procedure in children with PH. Performance of a lung biopsy has played a major role in understanding PH associated with CHD as is described in Chapter 66, and may help guide surgical management in select cases (67–71). In a series of children with CHD and PH assessed 1 year after repair, Rabinovitch et al. (71) compared pulmonary hemodynamics and morphometric changes. Hemodynamics normalized in all children repaired before 9 months of age, regardless of severity of the preoperative Heath-Edwards, morphometric, or hemodynamic changes. In contrast, in children with severe preoperative changes at lung biopsy (grade C morphometric, Heath-Edwards III), PAP and PVR remained significantly elevated if they were repaired after 2 years of age (71). The Heath-Edwards changes are heterogeneous, making absolute determination of being inoperable difficult (72).

Lung biopsy is indicated if there is a suspicion of another diagnosis that would be treated differently such as PVOD or PCH. Likewise, an increasing number of patients are being diagnosed with interstitial lung disease associated with PH. Examples include surfactant protein deficiency, such as ATP-binding cassette transporter A3 (ABCA3) deficiency, or capillaritis (73–76). These patients often do not respond to treatments currently available for PAH and thus need a definitive diagnosis for lung transplant listing. The evaluation of PH by lung biopsy is further described in Chapter 66.

Wedge angiography may provide clues to the severity of pulmonary vascular disease (70,77,78). Abnormalities of capillary blush are seen with mild elevation of PVR and may progress to the appearance of a “tree in winter” as disease progresses.

IMPORTANT CAUSES OF PH IN CHILDREN

Idiopathic Pulmonary Arterial Hypertension

PAH was first described by Dresdale in 1951 as a sporadic disease known as PPH. Subsequently, in 1954, Dresdale reported the familial transmission of PPH. PPH, currently named IPAH, is characterized by progressive and sustained elevations of PAP without a defined etiology. IPAH is a rare disease, which occurs most frequently in young adult females (79). While generally developing in the adult population, pediatric IPAH is well reported, and carried a dismal prognosis in a cohort from the National Institutes of Health, with a median survival of only 10 months in individuals <16 years old (80). Evaluation for IPAH in the pediatric age group is similar to that outlined for adults and is a diagnosis of exclusion, but increased scrutiny for the possibility of CHD is appropriate, and acute pulmonary vasoreactivity may be more common in children (81–84). Certain comorbidities, such as thyroid disease, an elevated antinuclear antibody, and lower airways obstruction are seen in children with IPAH (60,62,85).

Heritable—Familial Pulmonary Artery Hypertension

Between 6% and 12% of cases of IPAH may be familial in origin with an autosomal dominant pattern of inheritance (86).

Figure 67.4. Kaplan-Meier survival curves for children with IPAH and PAH associated with CHD. Survival curves are shown for all patients (left) and for the subgroup of IPAH patients (right) categorized with either BNP >180 pg/mL or <180 pg/mL. (From Bernus A, Wagner BD, Accurso F, et al. Brain natriuretic peptide levels in managing pediatric patients with pulmonary arterial hypertension. *Chest* 2009;135:745–751. Reproduced with permission from the American College of Chest Physicians.)

BMPR2 mutations present on chromosome 2 q31-32 have been identified in children and adults with IPAH and familial PAH (87–91). This genetic mutation in the TGF- β receptor family has been found in patients with familial PAH (50% to 70%) (87,89) and sporadic PAH (15% to 26%) (90). Currently, about 300 mutations in the *BMPR2* gene have been discovered (92). The pattern of inheritance in children with *BMPR2* mutations is the same as adults with an autosomal dominant pattern with reduced penetrance. Reduced penetrance implies that generations of mutation-carrying persons may not express the disease. Only 20% of individuals with a known *BMPR2* mutation will develop clinical PAH. HPAH may also be characterized as “genetic anticipation,” in which HPAH presented progressively earlier with subsequent generations. In families, it may be the child who presents first with severe disease, and then further evaluation of first-degree relatives reveals milder disease in the parents or grandparents (93).

The bone morphogenetic proteins (BMPs) are members of the TGF- β superfamily of receptors. BMPs play an important role in the development of the lungs, bone, and cartilage. BMP binds to the *BMPR1* receptor leading to heterodimerization with the *BMPR2* receptor. Activation of the receptor leads to phosphorylation of a series of cytoplasmic mediators, such as the SMAD proteins. In the BMP cascade, SMAD proteins 1/5/8 complex with SMAD 4 for translocation to the nucleus leading to target gene expression and inhibit cell growth and induction of apoptosis (Fig. 67.5) (87,94–103). A similar cascade is present for TGF- β signaling. It has been proposed that a second hit leads to a further decrease in BMP signaling and thus an imbalance/increase in proproliferative TGF- β signaling. Most forms of PAH are associated with abnormal *BMPR2* signaling, even if a defined mutation is not found.

BMPR2 mutations have been evaluated in several pediatric series with inconsistent results. Grunig et al. (88) found no *BMPR2* mutations or deletions in 13 children with IPAH. However, in a study by Harrison et al. (104), 22% of children with IPAH or PH associated with CHD had activin-like kinase type-1 (ALK-1) or *BMPR2* mutations. *BMPR2* mutations were found in only 6% of a mixed cohort of adults and children with

PAH and CHD (105). More recently, a study by Rosenzweig et al. (106) evaluated whether children and adults with PAH had a positive response to acute vasodilator testing. In this study, the authors found that *BMPR2* mutation-positive children appeared less likely to respond to acute vasodilator testing than mutation-negative children. Furthermore, these children had lower mixed venous oxygen saturation and cardiac index than those without a *BMPR2* mutation. These findings are similar to those by Elliott et al. (107) who reported that IPAH and FPAH adult patients with *BMPR2* mutations are less likely to respond to acute vasodilator testing than *BMPR2* mutation-negative patients. Recently, Sztrymf et al. (108) reported that patients with a *BMPR2* mutation presented at an earlier age, developed more severe disease, and died earlier. Mutations in other members of the TGF- β family, such as ALK-1 or endoglin have also been described as leading to PH in children (92,94,98,109,110).

The variable clinical expression with reduced penetrance makes genetic counseling difficult. As there is reduced penetrance, only 20% of carriers will develop the disease. A negative *BMPR2* testing result may be reassuring for a family member with a known *BMPR2* mutation. If negative, a family member's risk falls from 1 in 10 to that of the general population, which is about 1 in 1,000,000. It is mandatory that genetic testing be performed in conjunction with experienced genetic counselors before and after the test results (87).

Other genetic loci may also play important roles. Studies have suggested an important role of the serotonin transporter gene in some adults with PAH (111,112), and a study in children found that homozygosity for the long variant of the serotonin transporter gene was highly associated with IPAH in children (113).

Connective Tissue Disease

PAH complicates the course of some patients with connective tissue disease (CTD). The recent WHO classification recognizes PAH associated with CTD in Group 1 PAH, and CTD as one of the most common forms of PAH in adults. It is estimated that almost 30% of adult cases of PAH are associated with CTD, many with systemic sclerosis (114). Among these

Figure 67.5. Abnormalities of signaling by the transforming growth factor- β . TGF- β superfamily members play a major role in heritable PH. TGF- β can be divided into two main intracellular pathways according to the SMAD mediators: either SMAD2/3 or SMAD1/5/8. Members of the TGF- β family bind to specific Ser/Thr kinase type II and type I receptors; in most cells, TGF signals via TGFBR2 and ALK5 (also known as TGF receptor-1; TGFBR1), and BMPs signal via the BMP type II receptor (BMPR2) and ALK1, ALK2, ALK3, and ALK6. Activated type I receptors induce the phosphorylation of specific receptor-regulated (R-) SMADs, which are the intracellular effectors of TGF- β family members. In most cell types, TGF- β induces SMAD2/3 phosphorylation and BMPs induce SMAD1/5/8 phosphorylation. Activated R-SMADs form heteromeric complexes with SMAD4 that accumulate in the nucleus, where they regulate the expression of target genes. The imbalance of decreased BMPR2 signaling and increased TGF- β signaling leads to a proliferative state in PH. (From ten Dijke P, Arthur HM. Extracellular control of TGFbeta signaling in vascular development and disease. *Nat Rev Mol Cell Biol* 2007;8:857–869, with permission.)

patients, PAH is often multifactorial, including pulmonary fibrosis-related CTD and thrombosis associated with vasculitis and/or thrombophilia. PAH associated with CTD is also a major risk factor for death in these patients. Recently, various pulmonary vasodilator therapies have improved the prognosis for patients with PAH associated with CTD. Previous studies have shown that epoprostenol increases exercise capacity compared with conventional therapy in patients with PAH associated with systemic sclerosis (115) and improves hemodynamics and exercise capacity in patients with systemic lupus erythematosus (116). Pulmonary vasodilators have been used in these patients with some success. Management of the underlying CTD is crucial for successful management of the child with PAH and CTD (117).

Congenital Heart Disease

A variety of congenital cardiac lesions can cause PH (10) (Table 67.3). The age and type of lesion strongly contribute to the risk of developing irreversible pulmonary vascular disease. Early surgery has markedly decreased the development of late PAH and the propensity for postoperative pulmonary hypertensive crises. In general, patients with a ventricular septal defect (VSD) or patent ductus arteriosus (PDA) do not develop

irreversible pulmonary vascular changes before 2 years of age. Most centers perform early surgical repair in the first months of age to decrease the likelihood of pulmonary vascular disease. Without appropriate surgery an estimated 50% of patients with a large nonrestrictive VSD will develop Eisenmenger syndrome (118). Patients with an atrial septal defect (ASD) are less likely to develop severe PAH, and this usually occurs in the third to fifth decade. Infants with an ASD or VSD with concomitant chronic lung disease are at an increased risk for the early development of severe pulmonary vascular disease. In one study of infants with BPD who underwent cardiac surgery for the repair of CHD, 25% of those who died had PAH (119). In the Euro Heart survey of adults with CHD, 882 patients with a secundum ASD were identified. Hemodynamics was worse in nonoperated patients than the patients whose defects had been closed. In moderate or large defects, when not operated, clinical parameters tended to worsen with time. In adults with small ASDs, the patients did well and an operation was not necessarily indicated (120). Eisenmenger syndrome in adults with an ASD was rare and occurred in 15 of 896 patients in a different analysis of the data (121). The risk of PAH with a sinus venosus ASD is likely higher than that of a secundum ASD (122,123). Of the 1,877 patients in the survey, there were 710 with a VSD; the defect was closed

in 275, open without Eisenmenger syndrome in 352, and open with Eisenmenger syndrome in 83. Patients with cyanotic congenital cardiac lesions such as transposition of the great arteries, truncus arteriosus, and univentricular heart with high flow are more likely to develop rapid irreversible pulmonary vascular disease. Palliative shunting operations for certain cardiac anomalies designed to increase pulmonary blood flow also may lead to the subsequent development of PH.

Operability

In the child with CHD and pulmonary vascular disease, determination of baseline hemodynamics and reactivity to vasodilators is crucial for successful short-term and long-term outcome (69,71,124–133). A recent manuscript has extensively reviewed this topic (125). One of the most important factors in long-term survival and freedom from pulmonary vascular disease is the age at which surgery is performed. In 1984, Rabinovitch et al. (71) stated “early corrective surgery is the best safeguard against the persistence or progression of structural changes in the pulmonary vascular bed.” In their series, all children repaired before 9 months of age, regardless of severity of the preoperative Heath-Edwards, morphometric, or hemodynamic changes had normal PAP one year after surgery. Rabinovitch et al. (71) also noted that certain lesions, such as d-transposition of the great arteries, complete atrioventricular septal defect, and truncus arteriosus are more prone to the early development of severe pulmonary vascular changes than others (69,130). In general, surgery of the child with CHD is recommended before 2 years of age (134–136), but most centers will perform complete repair of the majority of lesions within the first months of life.

Cardiac catheterization aids in determination of PVR, pulmonary-to-SVR ratio (Rp/Rs), and pulmonary-to-systemic blood flow. However, several issues arise in the determination of hemodynamics in these patients. Viswanathan and Kumar (127) have described that the assessment of preoperative PVR and pulmonary vascular reactivity in the patient with CHD is difficult and is prone to error. Hemodynamic evaluation of these patients is a “snapshot” that may not represent the usual state of the patient. These studies are frequently performed under general anesthesia, which frequently leads to a lower systemic blood pressure than the precatheterization condition (58). Furthermore, the determination of oxygen consumption in children with CHD is problematic (137,138). Oxygen consumption is frequently estimated since direct measurement of oxygen consumption in intubated patients is not readily available due to lack of an FDA-approved device. The LaFarge equation introduces significant overestimation of oxygen consumption in ventilated patients with CHD of all ages, particularly in children younger than 3 years (137,138). Estimation rather than measurement of PaO_2 in the pulmonary veins leads to overestimation of pulmonary blood flow, and subsequently underestimation of the PVR. In patients with single-ventricle anatomy and physiology, additional problems arise. In patients with a bidirectional cavopulmonary anastomosis, the PAP is measured with less than a full cardiac output, thus the pressure after Fontan completion may not be similar. Furthermore, aortopulmonary collaterals are frequent in the single-ventricle patient leading to underestimation of pulmonary blood flow by catheterization. Patients with CHD may also have various degrees of pulmonary vein disease leading to inability to accurately measure PVR. This problem, in addition to the low cardiac output seen in pretransplant evaluation makes assessment of PVR in the pretransplant evaluation particularly difficult (139).

Although many studies have evaluated hemodynamics to determine operability, the precise values that best correlate with early and late outcome remain unclear. Many of these studies are not directly comparable due to differences in sedation and

the use of measured or assumed oxygen consumption. The first Natural History Study of VSD found that no child repaired under 2 years of age, regardless of Rp/Rs had an elevated Rp/Rs 4 to 8 years after surgery (136). Haneda et al. (135) reported similar findings. In 1982, Lock evaluated the pulmonary vascular response to oxygen in 25 children with large VSDs and elevated PVR. A positive preoperative response to oxygen, defined as a fall in the Rp/Rs of 30%, did not correlate with either operative survival or late Rp/Rs (140). In adult patients with an isolated ASD, Steele retrospectively evaluated patients with a total PVR $>7 \text{ U} \times \text{m}^2$. Total pulmonary resistance (TPR) (defined as mean PAP/pulmonary flow index) had the highest correlation with survival of the hemodynamic parameters measured. Of 18 surgically treated patients at 10-year follow-up, only 1 of 14 with TPR of $<15 \text{ U} \times \text{m}^2$, compared with three of four with TPR of $>15 \text{ U} \times \text{m}^2$ had died (122). Bush and colleagues in 1988 measured PVR and evaluated lung biopsies in 14 children with PH and CHD. Patients with a lowest PVR of $>6 \text{ U} \times \text{m}^2$ had a poor prognosis whatever their lung morphology, and some patients with Heath-Edwards grade I or II still had a high PVR. Other vasodilators, such as isoproterenol, were used in a study of 87 children and young adults with VSD. When resting PVR was $\leq 7.9 \text{ U} \times \text{m}^2$, it always decreased with isoproterenol and no postoperative problems were experienced in 21 patients (141). In 1991, Moller et al. (142) evaluated 290 patients who underwent closure of a VSD from 1954 to 1960. Death occurred in 59 patients, with higher mortality rates in those operated on after the age of 5 years, those with PVR $>7 \text{ U} \times \text{m}^2$, and those with complete heart block (Fig. 67.6) (142). More recently, Berner studied 13 children aged 6 months to 16 years with a baseline PVR of $>6 \text{ U} \times \text{m}^2$ and Rp/Rs of >0.3 at catheterization with inhaled nitric oxide (NO). Six of seven with a fall in PVR and Rp/Rs $>10\%$ and a value of Rp/Rs <0.3 survived (143). Inhaled NO, 80 ppm with oxygen, was studied by Atz et al. (144), and they showed that a response of 20% or more reduction in PVR was seen in 22/25 patients with NO+oxygen compared with 16/25 in oxygen alone. Of the 71 patients studied, 10 underwent surgery. In these patients, baseline PVR in room air was $12.9 \pm 1.9 \text{ U} \times \text{m}^2$ that decreased to $4.1 \pm 1.9 \text{ U} \times \text{m}^2$ in NO (144). In a collaborative study of 10 institutions, 124 patients with CHD were studied under conditions of room air, oxygen, and NO (145). Seventy four of these underwent surgery and 12 died or

Figure 67.6. VSD after surgery. Life table analysis of 168 patients divided into categories according to level of PVR before surgery. (From Moller JH, Patton C, Varco RL, et al. Late results (30 to 35 years) after operative closure of isolated ventricular septal defect from 1954 to 1960. *Am J Cardiol* 1991;68:1491–1497, with permission.)

Figure 67.7. Rp:Rs during preoperative testing according to outcome following surgery. In a combination of oxygen and nitric oxide, the lowest value of Rp:Rs that was associated with a poor outcome secondary to PH was 0.16. The highest value of Rp:Rs that was associated with a good outcome was 0.41. An optimal balance in sensitivity and specificity correlated with an Rp:Rs < 0.27 in a combination of oxygen and nitric oxide as criteria for operability. Rp, pulmonary vascular resistance index; Rs, systemic vascular resistance index. (From Balzer DT, Kort HW, Day RW, et al. Inhaled nitric oxide as a preoperative test (INOP test I): the INOP Test Study Group. *Circulation* 2002;106:176–181, with permission.)

developed right heart failure. When Rp/Rs of <0.33 was used as the criterion, sensitivity (64% vs. 97%) and accuracy (68% vs. 90%) were increased by using inhaled NO (iNO) in combination with oxygen compared with oxygen alone (Fig. 67.7). When iNO plus oxygen was used, the lowest value of Rp/Rs that was associated with a poor outcome was 0.16. The highest value of Rp/Rs that was associated with a good outcome was 0.41 (Fig. 66.7) (145). Most recently, Kannan et al. (146) in 2003 described long-term follow-up of 38 patients with an unrestricted VSD and elevated PVR $>6.9 \text{ U} \times \text{m}^2$ operated on at a median age 7.5 years (range, 6 months to 27 years), from 1985 to 1996 in India. Preoperative PVR, ratio of pulmonary blood flow to systemic blood flow, and Rp/Rs were 7.63 ± 1.8 Wood units, 1.9 ± 0.48 , and 0.41 ± 0.12 , respectively. Thirty patients (79%) had a good outcome and were asymptomatic at a mean follow-up of 8.7 years, with significant reduction in PAP. Eight patients (21%) had a poor outcome, but there was no significant difference regarding hemodynamic parameters at baseline between those who had a good outcome and those who did not (146). Importantly, Kumar et al. recommend a holistic approach that combines clinical, noninvasive, and invasive data to make a decision regarding operability in this challenging group of patients with shunt lesions and elevated PVR (127,147). This approach and an algorithm have recently been described by Lopes (147). Patients who are under 2 years of age with evidence of pulmonary overcirculation and exclusive left-to-right shunting by echo do not necessarily need to undergo cardiac catheterization prior to surgery. Those patients who are older and have desaturation or bidirectional shunting may benefit from vasodilator testing to stratify risk (Fig. 67.8). Several studies suggest that a baseline PVR or lowest PVR <7 to $8 \text{ Wood units} \times \text{m}^2$

predicts a good outcome, (125,141,142,148) although there are reports of good surgical outcomes with higher PVR. The role of longer-term “treatment and repair” or a period of pulmonary artery banding is less well defined but is intriguing (149).

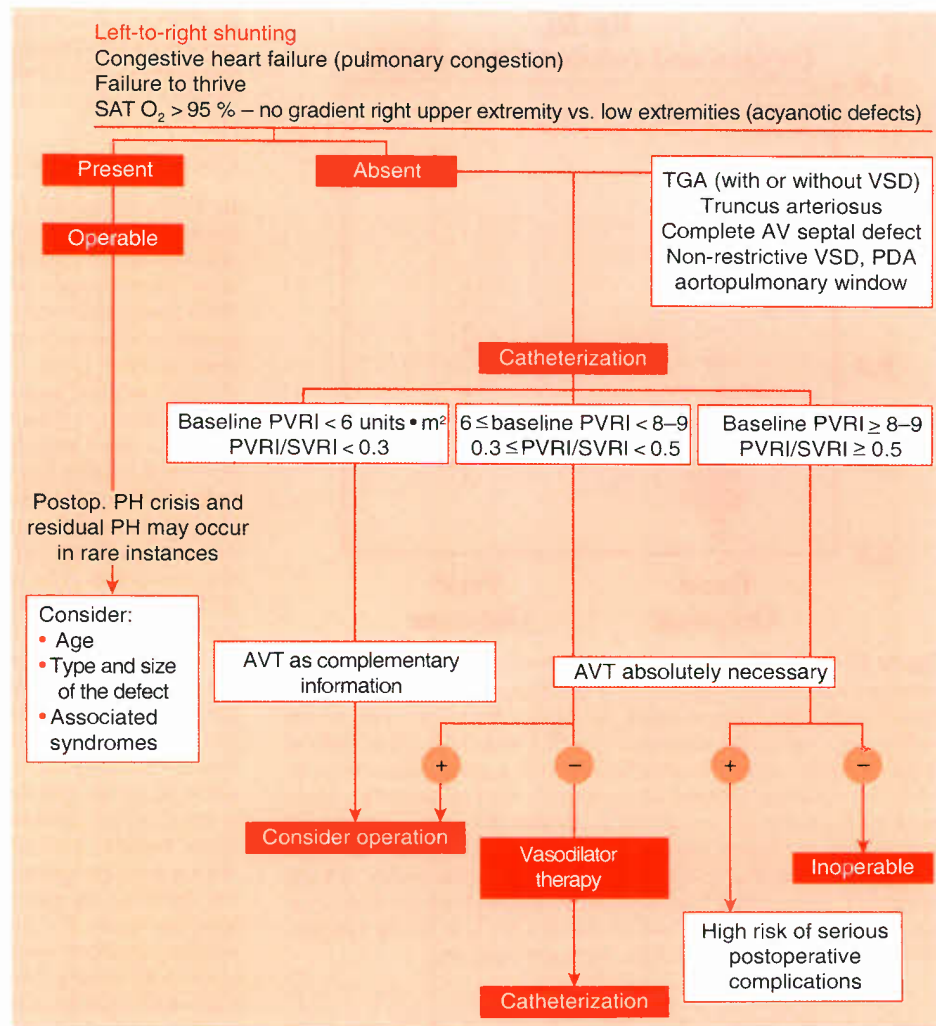

Eisenmenger Syndrome

In 1897, Viktor Eisenmenger described a 32-year-old cyanotic patient who died of massive hemoptysis and whose postmortem showed a VSD. Subsequently, Paul Wood, in 1958 used the term Eisenmenger complex to define the condition of a large VSD associated with increased PAP and PVR causing bidirectional or reversed (right-to-left) shunting and systemic oxygen desaturation (150). Currently, the term “Eisenmenger syndrome” is used more broadly to describe PH with a reversed central shunt (150–156). In general, the term Eisenmenger syndrome is used mainly for shunts distal to the tricuspid valve, but some studies have included patients with a large ASD. Elevated PVR and bidirectional or right-to-left shunting through a systemic-to-pulmonary connection, such as a VSD, PDA, univentricular heart, or aortopulmonary window, characterizes the syndrome. The most common lesions being VSD (33%), ASD (30%), and PDA (14%) in one series (157). The shunt is initially left-to-right, but as the underlying condition continues to increase PVR, there is a reversal of the shunt to a right-to-left configuration, leading to cyanosis and erythrocytosis. Some patients who are diagnosed with Eisenmenger syndrome do not have a prior history of congestive heart failure suggesting that PVR never fell to normal levels in the perinatal period. In general, the prognosis of patients with Eisenmenger syndrome is much better than for patients with IPAH, but syncope, right-heart failure, and severe hypoxemia are similarly associated with a poor prognosis. The RV plays a critical role in determining survival. In general, patients with Eisenmenger syndrome have favorable RV function until the later stages of the disease, whereas patients with late repair of CHD who develop PAH tend to do poorly. Morbidity in Eisenmenger syndrome is common and includes hemoptysis, pulmonary thromboembolism, stroke, and cerebral abscess. An increased risk of death has been shown to be related to noncardiac surgery with general anesthesia. Maternal mortality is estimated at 50% during the course of the pregnancy. Patients with complex heart disease and Eisenmenger syndrome tend to have earlier clinical deterioration and death compared to those with Eisenmenger syndrome related to an ASD, VSD, or PDA (158–160).

Red blood cell depletion may be utilized in Eisenmenger syndrome to provide temporary relief of major hyperviscosity symptoms or to improve perioperative hemostasis, but should not routinely be performed as this leads to increased stiffness of the red blood cell (161). Treatment of iron deficiency and routine monitoring of hemoglobin level are key elements of treatment and may improve exercise tolerance. Noncardiac operations on Eisenmenger patients are associated with a high mortality rate and should be managed by a multidisciplinary team experienced in the care of patients with this condition. Nocturnal oxygen therapy in Eisenmenger syndrome does not appear to alter long-term outcome (162).

Therapy for Eisenmenger syndrome has evolved over the last decade (163–165). The Bosentan Randomized Trial of Endothelin (ET) Antagonist Therapy-5 (BREATHE-5) was a 16-week, multicenter, randomized, double-blind, placebo-controlled study evaluating the effect of bosentan, a dual ET receptor antagonist (ERA), on systemic pulse oximetry (primary safety end point) and PVR (primary efficacy end point) in patients with WHO functional class III Eisenmenger syndrome. The placebo-corrected effect on systemic pulse oximetry was 1.0% (95% confidence interval, -0.7 to 2.8), demonstrating that bosentan did not worsen oxygen saturation. Compared with placebo, bosentan reduced PVR

Figure 67.8. An algorithm of preoperative evaluation and management of pediatric patients with congenital cardiac shunts. Proposed criteria for a pulmonary vasodilator response to be considered as positive: $\geq 20\%$ decrease in PVRI and Rp/Rs ratio from baseline, with respective final (lowest) values of <6 Wood units \times m^2 and <0.3 . Criteria for patient assignment to palliative surgery are not suggested. The routine is not applicable to complex conditions such as the absence of a subpulmonary ventricle (candidates to cavopulmonary anastomoses). AVT, acute pulmonary vasoreactivity test; PDA, patent ductus arteriosus; PVRI, pulmonary vascular resistance index; SVRI, systemic vascular resistance index; TGA, transposition of great arteries; VSD, ventricular septal defect. (From Lopes A. Pre-operative pulmonary hypertension in congenital heart disease and aspects of Eisenmenger's syndrome in children. In: Beghetti M, ed. *Pediatric Pulmonary Hypertension*. Munich, Germany: Elsevier Urban & Fischer, 2011, with permission.)

and mean PAP and increased exercise capacity by 53.1 m (164). Patients with Eisenmenger syndrome due to an ASD or VSD were equally likely to improve (166). In a separate study, in children on bosentan a progressive decline in exercise capacity was observed from 1-year follow-up, whereas in the adults, improvement lasted longer (167). A recent retrospective study evaluated the use of advanced therapies (ATs), such as type 5 phosphodiesterase (PDE-5) inhibitors, prostanooids or ERAs, in 229 patients (aged 34.5 ± 12.6 years). The majority had complex anatomy, and 53.7% were in New York Heart Association class \geq III at baseline assessment. Sixty-eight patients either were on AT or had AT initiated during follow-up. During a median follow-up of 4.0 years, 52 patients died, only two of them while on AT. Patients on AT were at a significantly lower risk of death by propensity score regression adjustment (C statistic = 0.80; hazard ratio, 0.16; 95% confidence interval, 0.04 to 0.71; $p = 0.015$) (Fig. 67.9) (165). ATs should be considered when other causes of functional limitation, such as iron deficiency, have been first addressed (168).

HEPATOPULMONARY SYNDROME AND PORTOPULMONARY HYPERTENSION

Hepatopulmonary syndrome (HPS) and PPHTN are distinct pulmonary vascular complications of hepatic and extrahepatic portal hypertension (169–172). HPS is defined as dilated

pulmonary capillaries and precapillary arteriovenous malformations resulting in intrapulmonary vascular shunting, ventilation–perfusion mismatching, and chronic hypoxemia in the setting of liver disease or portal hypertension. PPHTN is defined as PAH with an elevated mean PAP and increased PVR caused by a pulmonary arteriopathy in the setting of portal hypertension and in the absence of underlying cardiopulmonary disease (171,173). PPHTN and HPS are estimated to occur in 2% to 10% and 4% to 29%, respectively, of adults with cirrhosis (174). Both PPHTN and HPS are associated with increased morbidity and mortality and are significant risk factors for requiring orthotopic liver transplantation (OLT) (175,176). However, resolution of both disorders is possible after successful OLT (175,176). PPHTN and HPS have been reported in children with portal hypertension from both cirrhosis and congenital or acquired portal vein abnormalities; however, the incidence of these complications in children is unknown (15,16). An autopsy study of children with portal hypertension found 5.2% of cases with severe PH. All were females in late childhood or adolescence with idiopathic portal hypertension (177).

The pathogenesis of PPHTN and HPS remains unknown. Proposed theories suggest that these disorders result from a combination of hyperdynamic circulation, increased cardiac output, sheer injury to vascular walls, and an imbalance of circulating vasoactive peptides (178,179). Abnormal hepatic synthesis of vasoactive peptides, such as ET-1, or impaired hepatic metabolism of intestinally derived endotoxins, cytokines, and neurohormones may result in these substances reaching the pulmonary vascular bed via portosystemic shunting, directly altering

Figure 67.9. A: Unadjusted survival rate curves (with 95% CIs) by treatment with ATs in adults with Eisenmenger syndrome AT ($n = 287$). P value refers to Cox model. B: Adjusted survival rate curves, based on the propensity score-adjusted Cox model, of patients within the third propensity score quartile, with and without advanced therapy. (From Dimopoulos K, Inuzuka R, Goletto S, et al. Improved survival among patients with Eisenmenger syndrome receiving advanced therapy for pulmonary arterial hypertension. *Circulation* 2010;121:20–25, with permission.)

vessel tone or leading to pulmonary vascular inflammation and remodeling. Recent studies have highlighted the potential role of vascular endothelial growth factor and hypoxia inducible factor in the development of vascular dilation and arteriovenous malformations (180–184). The resulting pathology is strikingly different in these two disorders with vasodilation of pulmonary arterioles and capillaries causing arteriovenous shunting in HPS and intimal fibrosis with endothelial and smooth muscle cell proliferation leading to increased PVR in PPHTN.

Patients with elevated RV systolic pressure estimated by echocardiography should undergo confirmatory right heart catheterization (175,176). In children, a dilated pulmonary artery on chest radiograph and loud second heart sound are suggestive of PH, whereas the EKG is not uniformly abnormal (15). In children, the initial clinical presentation is subtle with the initial presentation rarely being death from a pulmonary hypertensive crisis (185).

PPHTN is frequently resistant to many first-line medications. If the diagnosis of PPHTN is made early prior to the development of irreversible pulmonary vasculopathy, then liver transplantation can be successfully performed and may reverse the process of PPHTN. Similar to adults, few patients with PPHTN respond to calcium channel blocker therapy. In more severe cases treatment with epoprostenol is used, in addition to other targeted PAH agents (15,174,176).

HUMAN IMMUNODEFICIENCY VIRUS

Since the first description by Kim et al. (186), the association between PAH and HIV infection has been well established; there are multiple reports for adult patients (187,188) whereas little is known about the incidence, clinical outcome, and therapy options for children (189,190). Most children with HIV are infected in the perinatal period (191). Pongprot et al. (190) detected PH in 41% of their highly selected cohort of HIV-infected children. The pathogenesis of HIV-PAH is not completely understood. It has been hypothesized that the

HIV infection may damage the cells by stimulating the host to release proinflammatory cytokines, growth factors, or ET-1 that would result in PAH (192). HIV Nef, an accessory HIV protein, may play a role in the development of PH. The prognosis of HIV-PAH is limited but seems to improve in adults with highly active antiretroviral therapy (HAART). However, the efficacy of HAART in patients with HIV-related PAH in general and, in the pediatric population more specifically, is still uncertain (188,193).

HEMOGLOBINOPATHIES

PH is a known complication of many hereditary hemolytic anemias including sickle-cell disease, thalassemia, and spherocytosis (194). Echocardiographic studies have estimated an incidence of PAH in 20% to 30% of patients with sickle-cell disease screened (195,196). Furthermore, recent studies have shown that up to 75% of adults with sickle-cell disease may have physiologic evidence of PH at the time of death. Gladwin et al. (195) studied 195 adults with sickle-cell disease and found a 32% prevalence of PH. The mortality of those with PH was 40% at 45 months whereas mortality was only 2% at 45 months in those without PH. PH was defined as a Doppler-derived tricuspid regurgitation (TR) velocity of >2.5 m/s. A mild elevation of RV systolic pressure carried a >10 -fold risk of death in adults with PH. Data in children with sickle cell disease are lacking, but recent studies have begun to evaluate the prevalence and risk factors for PH (194,197–201).

In a study by Pashankar et al. (196), screening echocardiograms were performed in children over 6 years of age with homozygous SS or thalassemia. When using a definition of PH as a PASP >30 mm Hg, corresponding to a peak of TR velocity ≥ 2.5 m/s, 30% of patients had elevated TR jet velocity ≥ 2.5 m/s. Furthermore, one-third of these patients had TR >3 m/s. Almost all patients with an elevated TR jet velocity had hemoglobin homozygous SS disease. Factors associated with elevated PAP included a high reticulocyte count, low oxygen saturation,

and a high platelet count. Interestingly, neither the incidences of acute chest syndrome, hydroxyurea therapy, blood transfusion, or stroke, nor hemoglobin and bilirubin levels between patients with and without elevated PAP were different. Furthermore, in patients with an elevated TR velocity, transcranial Doppler examinations were normal (196). Further study by Pashankar et al. (202) followed patients with echocardiographic evidence of PAH. Those with a TR velocity $>3\text{m/s}$ were offered treatment with hydroxyurea; a normalization of TR velocity was seen in 8 of 19 patients treated with hydroxyurea.

In children as well as adults with sickle cell disease, PH is likely due to multifactorial causes such as left ventricular diastolic dysfunction and/or thromboembolic disease due to hypercoagulability (203,204). Frequently, patients with an elevated TR velocity have elevated cardiac output and normal PVR at catheterization. However, it is important to note that viscosity, that is, hemoglobin, may affect PVR, and viscosity is rarely considered in the calculation of PVR (205). Intravascular hemolysis may lead to release of hemoglobin, which reacts with and destroys NO (206) (Fig. 67.10). Likewise, arginase released from the erythrocyte degrades arginine and thus further reduces NO formation through arginine (197,206). Xanthine oxidase may also lead to a decrease in NO. This reduced NO bioavailability leads to a cascade of other events that further exacerbates PH and includes an increase in ET, an increase in activation of adhesion molecules, and activation of platelets (207). Due

to abnormalities of NO, sildenafil is being studied as a potential therapy for treatment of PAH associated with sickle cell disease (208,209). However, caution is needed. The National Heart, Lung, and Blood Institute of the National Institutes of Health stopped a recent clinical trial testing sildenafil treatment for PH in adults with sickle cell disease nearly one year early due to safety concerns. Compared to participants on placebo, participants taking sildenafil were significantly more likely to have serious medical problems, such as sickle cell crises (NIH News, July 28, 2009).

PULMONARY CAPILLARY HEMANGIOMATOSIS AND PULMONARY VENO-OCCLUSIVE DISEASE

PCH and pulmonary veno-occlusive disease (PVOD) both are characterized by precapillary PAH and are included in WHO classification group 1 (210–215). These disorders differ in that treatment of these disorders may differ from many of the other WHO group 1 diagnoses, and thus are in a separate category in the new WHO classification. In particular, vasodilators may worsen pulmonary edema in PCH and PVOD (212,216). Furthermore, these two disorders may be difficult to diagnose and are frequently found at autopsy (217). Both PVOD and PCH are characterized by widespread vascular obstruction at either the alveolar capillary bed (PCH) or the pulmonary venules and

Figure 67.10. Mechanisms of pulmonary vascular dysfunction in hemoglobinopathies. (From Gladwin MT, Kato GJ. Cardiopulmonary complications of sickle cell disease: role of nitric oxide and hemolytic anemia. *Hematology Am Soc Hematol Educ Program* 2005:51–57, with permission.)

small veins (PVOD) (214,215). Treatment of either PVOD or PCH has been frequently unsuccessful and may require lung or heart/lung transplantation. In both disorders, the definitive diagnosis is usually made by surgical lung biopsy. Clues to the diagnosis of PVOD and PCH may lie in underlying pulmonary edema on chest radiograph and these findings may worsen with the initiation of either oxygen or inhaled NO. Characteristic findings may be seen on a chest CT scan and include central pulmonary artery prominence with widespread interlobular septa in the case of PVOD as well as ground-glass opacities. In PCH, the chest radiograph demonstrates enlarged central pulmonary arteries as well as a reticulonodular or micronodular areas of opacity, which may be seen on chest radiograph but are more prominent on the chest CT (215). Likewise, in both of these disorders pulmonary arteriograms may appear normal, particularly if the PVOD is microvascular in nature and not associated with larger vessel pulmonary vein disease. However, PVOD is rare in the spectrum of pulmonary vein abnormalities usually seen in children. In both disorders, PAP is elevated, and may be suprasystemic in patients with PVOD. Likewise, the pulmonary capillary wedge pressure is frequently normal in both disorders.

Clinical experience has shown that potent vasodilators (including continuous intravenous prostacyclin [PGI₂] and calcium channel blockers) induce florid and even fatal pulmonary edema in patients with either PVOD or PCH. To exclude unsuspected radiologic evidence of PVOD or PCH, it is currently suggested that patients with presumed IPAH should undergo a high-resolution CT examination before initiation of vasodilator therapy. Therapy for these disorders is limited and is not uniformly effective. Lung transplantation is the only curative option. However, trials of anticoagulation and steroids have been attempted in children with PVOD with mixed results. Due to the findings of myofibroblasts seen in patients with pulmonary vein disorders investigators have attempted use of chemotherapeutic agents with mixed results (218). In general, vasodilator therapy is unsuccessful, frequently contraindicated, and may worsen the patient status (108). In the case of PCH, experimental therapies have included alpha interferon (219), doxycycline (220), or possibly platelet-derived growth factor (PDGF) antagonists.

LEFT HEART DISEASE

Pulmonary venous hypertension may be caused by increased pressure anywhere between the pulmonary veins within the lung and the left ventricle. Adatia et al. (221) have recently reviewed left heart disease in children. Left heart disease in adults is common, particularly in the later part of life and is mainly due to left ventricular diastolic dysfunction. However, in children, structural heart disease, such as in Shone's complex or borderline small left ventricular physiology, is the most common. In addition, congenital and acquired cardiomyopathies are common causes of left heart disease and PH.

Paul Wood described three important mechanisms in the pathophysiology of PH secondary to mitral stenosis, which can be applied to most forms of PH due to left heart disease (222–225). First, there is a passive increase in PAP as downstream pressure increases to maintain left-sided preload and cardiac output. The pulmonary artery diastolic pressure is similar to the left atrial and left ventricular end diastolic pressure (LVEDP) in the absence of structural mitral disease. Therefore, the TPG and PVR are low (TPG <10 mm Hg, PVR <2.5 to 5 Wood units \times m²). Second, there is reflex vasoconstriction of the pulmonary arteries or veins or both. The diastolic PAP will be higher than the left atrial or LVEDP. Vasodilators, such as NO, will decrease the pulmonary artery diastolic pressure

to equal LVEDP (Fig. 67.11). The TPG will be >10 mm Hg and PVR >2.5 to 5 Wood units \times m². The use of pulmonary vasodilators in the setting of pulmonary vein disease, mitral stenosis, or an elevation of LVEDP may lead to pulmonary edema (128, 226–228). Reflex vasoconstriction is protective in some circumstances as described by Paul Wood, who observed that patients with mitral stenosis and elevated PVR had few symptoms of pulmonary edema (222). Third, there may be fixed pulmonary artery or vein obstruction. If there is fixed pulmonary vascular disease, there will be little or no change in pulmonary artery hemodynamics in response to inhaled NO. Frequently, a combination of all three mechanisms contributes to PH (221).

Pulmonary vein disease is a particularly vexing problem. Despite surgical, medical, and catheter-based attempts, often these therapies are ineffective with recurrence of disease and no cure (229–235). “Sutureless” repair of pulmonary vein stenosis after repair of total anomalous pulmonary venous return is more likely to be successful than in native pulmonary vein disease (236–239). Jenkins et al. (231) have described the expression of endothelial and smooth muscle cell markers in children with pulmonary vein stenosis. They noted strong staining of smooth muscle markers and receptor tyrosine kinases (RTK), such as PDGF receptor-alpha and -beta, fibroblast growth factor receptor (FGFR), and vascular endothelial growth factor VEGFR-2, suggesting that these cells are myofibroblast like (233). Studies are underway to target the RTK pathway.

RESPIRATORY DISEASE

Parenchymal lung disease is an important cause of PH in many patients. Complications include hypoxic pulmonary vasoconstriction causing increased PAP and can lead to RV hypertrophy and failure. RV function is usually preserved until disease is advanced. In most cases, correction of hypoxia can lead to reversal of PH. However, the development of cor pulmonale carries a poorer prognosis for reversibility.

Treatment of cor pulmonale depends on the precise etiology of lung disease, as well as disease severity. Nocturnal oxygen administration may alleviate hypoxia, typically without causing hypercapnia. Disorders of respiratory mechanics may also lead to hypoxia and the development of PH, as can BPD (240). More recent studies have suggested that abnormalities of the pulmonary vasculature may be a primary rather than secondary cause of abnormal alveolarization in BPD (241,242).

Of the chronic lung diseases associated with pediatric PH, BPD is the most common (243). BPD is described as chronic lung disease of infancy that generally occurs in prematurely born infants who have been treated with mechanical ventilation and oxygen therapy for acute respiratory distress syndrome. Northway and colleagues in 1967 defined BPD by the presence of persistent respiratory signs and symptoms, the need for supplemental oxygen to treat hypoxemia, and an abnormal chest radiograph at 36 weeks postmenstrual age. The introduction of prenatal steroid use, surfactant therapy, new ventilator strategies, and aggressive management of the PDA changed the clinical course and outcomes of premature newborns. This “new BPD” often develops in extremely low gestational age newborns who may have required minimal or even no ventilator support and low inspired oxygen concentrations. Despite these changes in the course of the premature infant, PH in BPD continues to contribute to significant morbidity and mortality. In premature infants (<32 weeks of gestation) with BPD who were diagnosed as having PAH at a median age of 4.8 months, Khemani et al. (244) found that the mean PAP was 43 ± 8 mm Hg and the PVR was 9.9 ± 2.8 Wood units. Survival rates were $64\% \pm 8\%$ at 6 months and $53\% \pm 11\%$ at 2 years after

Figure 67.11. An example of reflex pulmonary vasoconstriction in a 5-year-old patient with restrictive cardiomyopathy. A: Simultaneous PAP (85/45 mm Hg) and LVED pressure (23 mm Hg) at baseline. B: After inhaled NO abolishes the vasoconstrictive element the simultaneous PAP (55/25 mm Hg) and LVED pressure (25 mm Hg). (Reprinted from Adatia I, Kulik T, Mullen M. Pulmonary venous hypertension or pulmonary hypertension due to left heart disease. *Prog Pediatr Cardiol* 2009;27:35–42, with permission from Elsevier.)

diagnosis of PAH (Fig. 67.12). PAH and small birth weight for gestational age were associated with worse survival rates. Among 26 survivors PAH was improved in 89%.

Before vasodilator therapy is started, a complete evaluation of all causes of lung disease and its associated comorbidities should be done (245). This includes an extensive evaluation

Figure 67.12. Kaplan-Meier graph demonstrating the probability of survival from the time of diagnosis of PAH for patients with BPD and PAH in patients with severe PAH at any time ($n = 18$) and those with less-than-severe PAH ($n = 24$). (Reproduced with permission from Khemani E, McElhinney DB, Rhein L, et al. Pulmonary artery hypertension in formerly premature infants with bronchopulmonary dysplasia: clinical features and outcomes in the surfactant era. *Pediatrics* 2007;120:1260–1269, Copyright © 2007 by the AAP.)

for chronic reflux and aspiration, structural airway abnormalities (such as tonsillar and adenoidal hypertrophy, vocal cord paralysis, subglottic stenosis, and tracheomalacia), and assessments of bronchoreactivity (243). Cardiac catheterization is recommended for patients with BPD who: (a) have persistent signs of severe cardiorespiratory disease or clinical deterioration not directly related to airways disease, (b) are suspected of having significant PH despite optimal management of their lung disease and associated morbidities, (c) are candidates for chronic PH drug therapy, or (d) have unexplained, recurrent pulmonary edema. The goals of cardiac catheterization are to assess the severity of PH; exclude or document the severity of associated anatomic cardiac lesions; define the presence of systemic–pulmonary collateral vessels, pulmonary venous obstruction, or left heart dysfunction (246); and to assess pulmonary vascular reactivity in patients who fail to respond to oxygen therapy alone (243). Pulmonary vein stenosis is common in children with BPD and PH (229). Management of children with pulmonary vein stenosis is difficult as catheter-based intervention or surgery has shown poor long-term results and overall survival is poor with the 2-year survival rate from diagnosis of 43% (229). Left ventricular diastolic dysfunction may complicate the course of the infant with BPD with cardiac catheterization being required for certain diagnosis (246).

Patients with CDH are at risk for PH, which can develop at any phase of the disease (247–251). In addition to lung hypoplasia, patients with CDH may develop pulmonary artery or pulmonary vein stenosis (250). Infants with CDH and poor outcome have higher plasma ET-1 levels and severity of PH than infants with better outcomes (249).

THROMBOEMBOLIC DISEASE

Chronic thromboembolic disease as a cause of PH in children is rare, but an accurate diagnosis is essential for treatment

(252,253). Predisposing factors include antiphospholipid antibody syndrome, bacterial endocarditis, and ventriculoatrial shunt for the treatment of hydrocephalus. Likewise, the use of oral contraceptive agents may cause hypercoagulability, leading to pulmonary thromboembolic phenomena.

The diagnosis of chronic thromboembolic PH in children requires a high index of suspicion, as well as evaluation by ventilation perfusion, CT scanning, or angiography. In adults with chronic thromboembolic PH, surgically accessible disease, and no severe comorbidities, pulmonary thromboendarterectomy has been demonstrated to improve survival and quality of life (254). A similar approach should be considered for children who develop this condition despite the relative paucity of data on this procedure in the pediatric age group.

PHARMACOLOGIC THERAPY OF PULMONARY ARTERIAL HYPERTENSION

Based on known mechanisms of action, three classes of drugs have been extensively studied for the treatment of PAH: prostanooids (epoprostenol, treprostinil, iloprost, beraprost), ERAs (bosentan, ambrisentan), and type 5 phosphodiesterase (PDE-5) inhibitors (sildenafil, tadalafil) (Fig. 67.13). Without therapy, and sometimes despite appropriate surgical correction of congenital cardiac lesions, PAH progresses at a variable rate. As

vasoconstriction is an important component in the development of medial hypertrophy, vasodilators are frequently used to decrease PAP, improve cardiac output, and potentially reverse some of the pulmonary vascular changes noted in the lung. The long-term strategy for the treatment of PH in children (Fig. 67.14) (255) is similar to adults (Fig. 67.15), except that it is difficult to place young children in the WHO classification. Therapy in adults is evidence based whereas in children it is based on experience. Targeted PH therapy has empirically improved survival in most forms of PAH (Fig. 67.16A), except that severe PH after complete repair of CHD continues to have a worse prognosis (Fig. 67.16B).

Before commencing vasodilator therapy for chronic PAH, vasodilator responsiveness should be assessed in the cardiac catheterization unit. A positive response is defined by assessing the change in hemodynamic parameters to vasodilators. The younger the child at the time of testing, the greater the likelihood of acute pulmonary vasodilation in response to vasoreactivity testing (81,144,256). Many oral and inhaled vasodilators have been used for testing of vasodilator responsiveness (129,143,144,256–261).

CONVENTIONAL THERAPY

Conventional therapy in patients used to treat RV failure is frequently used in PAH in children. Digoxin is used in the presence of RV failure, although there are no clear-cut data in

Figure 67.13. The nitric oxide, prostacyclin, and endothelin system signaling pathways and targets for therapy in PH. (From Diller GP, Baumgartner H. Pulmonary arterial hypertension in adults with congenital heart disease. *Int J Clin Pract Suppl* 2010;13–24, with permission.)

Figure 67.14. Treatment algorithm in children with severe PAH. (Reprinted from Tissot C, Ivy DD, Beghetti M. Medical therapy for pediatric pulmonary arterial hypertension. *J Pediatr* 2010;157:528–532, with permission from Elsevier.)

children (262). Diuretics are used to treat peripheral edema or ascites in the presence of right heart failure; however, excessive diuresis should be avoided. Careful attention to respiratory tract infections is required as this may worsen alveolar hypoxia, and routine influenza vaccination is recommended. The use of decongestants with pseudoephedrine or other stimulant-type medications is discouraged as these have been associated with PAH (263). In children who require the use of oral contraceptive agents either for prevention of pregnancy or for regulation of menses, we recommend agents that have no estrogen content. Pulse oximetry and polysomnography are indicated and chronic hypoxemia or nighttime desaturation is aggressively treated. However, oxygen therapy is not used as a mainstay of therapy in children with normal daytime saturations.

ANTICOAGULATION

In retrospective trials in adults with IPAH, the use of warfarin has been associated with improved survival. Although the use of chronic anticoagulation has not been studied widely in children, it is usually recommended in IPAH, and particularly in those with an indwelling central catheter. During treatment with warfarin the aim is to maintain an INR between 1.5 and 2.0. The use of anticoagulation in patients with Eisenmenger syndrome or other forms of PH is controversial and the potential risks and benefits of anticoagulation in this setting must be carefully weighed.

VASOREACTIVITY TESTING

As in adults, cardiac catheterization with acute vasodilator testing is essential prior to selecting targeted therapy in children. Cardiac catheterization carries a greater risk in those children with baseline suprasystemic PAP (Odds Ratio = 8.1, $p = 0.02$) (56,57). As in adults, a short-acting vasodilator is used, such as inhaled NO (144,264,265). The conventional pediatric definition of a response to acute vasodilator testing for determination of suitability for calcium channel blockade is a 20% fall in mean PAP and PVR to a vasodilator agent with no change or an increase in cardiac output (82). Note that this is not the definition for operability (see above Operability). Because patients treated with calcium channel blockers began to fail this therapy, Sitbon et al. (266) established more stringent criteria for defining acute vasoreactivity in adults. Their definition mandated a fall in mean PAP >10 mm Hg to <40 mmHg to predict long-term response to calcium channel blocker therapy. Although more strict criteria are used in children, this has not been adequately studied in this population. Recent data have shown that 7% to 35% of children with IPAH and 6% of those with APAH are responders to acute vasodilator testing (267).

CALCIUM CHANNEL BLOCKERS

The use of calcium channel blockers to evaluate vasoreactivity has significant potential risks, as these drugs can cause a decrease in cardiac output or a marked drop in systemic

Figure 67.15. Treatment algorithm in adults with severe PAH. In: *Pulmonary Arterial Hypertension GUIDELINES Pocketcard™*. Figure 67.16. A: Survival curves for idiopathic pulmonary arterial hypertension (IPAH) and associated pulmonary arterial hypertension (APAH) cases censored for time in the study and for transplantation. There was no significant difference between the two groups. B: Survival curves for the subgroups within the APAH group. The number in each group (*brackets*) and the predicted survival out of a possible 5 years are shown. (Reproduced from Haworth SG, Hislop AA. Treatment and survival in children with pulmonary arterial hypertension: the UK Pulmonary Hypertension Service for Children 2001–2006. *Heart* 2009;95:312–317, with permission from BMJ Publishing Group Ltd.)

blood pressure (252). Such deleterious effects may be prolonged due to the relatively long half-life of calcium channel blockers. Consequently, elevated right atrial pressure and low cardiac output are contraindications to acute or chronic calcium channel blockade. The number of patients treated with calcium channel blockers is steadily decreasing. An acute trial of calcium channel blocker therapy should be performed only in those patients who are acutely responsive to either NO or PGI₂. Likewise, patients who do not have an acute vasodilatory response to short-acting agents and who are then placed on calcium channel blocker therapy are unlikely to benefit from this form of therapy (82). Eighty percent of children with severe PH are nonresponsive to acute vasodilator testing, and therefore require therapy other than calcium channel blockers.

PROSTACYCLINS

Adults with IPAH and children with CHD demonstrate an imbalance in the biosynthesis of thromboxane A₂ and PGI₂ (268). Likewise, adults and children with severe PH show diminished PGI₂ synthase expression in the lung vasculature (269). PGI₂ and PGI₂ analogues stimulate the cyclic-AMP pathway to increase pulmonary vasodilation. Intravenous PGI₂ was first used in the 1980s and continues to be the standard for treatment of severe PH with right heart failure. Epoprostenol was FDA approved in 1995. PGI₂ administered over the long term, utilizing intravenous epoprostenol, has shown to improve survival and quality of life in adults

and children with IPAH (82,270–272). Barst et al. (82) have shown improved survival in children treated with long-term intravenous epoprostenol, with a 4-year survival rate for treated children of 94% (Fig. 67.17), whilst Yung et al. (84) have reported a 10-year treatment success rate (freedom from death, transplantation, or atrial septostomy) of 37%. However, the treatment of patients with PGI₂ is cumbersome. Intravenous PGI₂ must be infused 24-hours/day via a central venous catheter and kept cold with ice packs; the half-life of the drug is 2 to 5 minutes, placing the patient at risk for an acute pulmonary hypertensive crisis if there is an accidental discontinuation of the medication. In addition, the side effects of the drug include nausea, diarrhea, jaw pain, bone pain, and headaches. Complications like line sepsis, local infection, and catheter dislodgement are not unusual and can be responsible for life-threatening rebound PH (273,274). Recently, the use of specific closed hub systems has been described in children to decrease the risk of catheter-related infection (275). Some children with an exceptional response to intravenous epoprostenol may wean from intravenous to oral therapy (47,276). Inhaled PGI₂ has been used in the critical care setting (277). A generic form of epoprostenol has been developed as well as a form that is stable at room temperature.

The PGI₂ analog treprostinil was approved by the FDA, initially for subcutaneous use (2002), and more recently for intravenous administration (2004) and inhaled administration (2009). Subcutaneous treprostinil allows patients to remain free of central venous catheters, and recent data have shown long-term efficacy in adults with PAH (278). Treprostinil has also been given in the intravenous form. Intravenous

Figure 67.17. Kaplan-Meier curves for survival and treatment success in children with IPAH who received epoprostenol ($n = 35$). Survival rates at 1, 3, 5, and 10 years were 94%, 88%, 81%, and 61%, respectively; treatment success rates at 1, 3, 5, and 10 years were 83%, 66%, 57%, and 37%, respectively. (From Yung, D, Widlitz AC, Rosenzweig EB, et al. Outcomes in children with idiopathic pulmonary arterial hypertension. *Circulation* 2004;110:660–665, with permission.)

treprostinil requires central line access and continuous infusion, but is easier for families to mix, and has a half-life of 4 hours. Intravenous treprostinil has fewer side effects than intravenous epoprostenol, but there are no studies comparing efficacy (279). In its subcutaneous form, discomfort at the infusion site is common and represents a limiting factor. However, a recent study of subcutaneous treprostinil in young children showed promise with tolerable side effects (280). Treprostinil has also been studied in an inhaled form (281) and studies are being performed in children.

An inhaled PGI₂ analog iloprost, received approval for the treatment of PAH in the United States in 2004. This medication is administered by nebulization 6 to 9 times a day. Iloprost requires patient cooperation with the treatment administration lasting 10 to 15 minutes, which is difficult for young children (256,282,283). The advantage of an inhaled PGI₂ is that it can cause selective pulmonary vasodilation without affecting systemic blood pressure. Additionally, inhaled PGI₂ analogues can improve gas exchange and intrapulmonary shunt in cases of impaired ventilation/perfusion by redistributing pulmonary blood flow from nonventilated to ventilated, aerosol-accessible lung regions (283,284). In children with CHD and PAH, inhaled iloprost may be as effective in lowering PAP and PVR as inhaled NO, and thus may be useful in evaluation of acute vasoreactivity (283). Inhaled iloprost has also been studied in combination with bosentan and sildenafil, among others (285–287).

Beraprost is an orally active PGI₂ analog with a half-life of 35 to 40 minutes. While beneficial effects have been noted in short-term trials, these may be attenuated with prolonged treatment (288,289). Data in children are scarce and beraprost is not available in the US or Europe but is used in Japan (288). Long-acting beraprost has recently been approved for adult PAH in Japan (289).

ENDOTHELIN

Another target for treatment of PH is the vasoconstrictor peptide ET(290). The ETs are a family of isopeptides consisting of ET-1, ET-2, and ET-3. ET-1 is a potent vasoactive peptide

produced primarily in the vascular endothelial cell, but also may be produced by smooth muscle cells. Two receptor subtypes, ET_A and ET_B, mediate the activity of ET-1. ET_A and ET_B receptors on vascular smooth muscle mediate vasoconstriction, whereas ET_B receptors on endothelial cells cause release of NO and PGI₂, and act as clearance receptors for circulating ET-1. ET-1 expression is increased in the pulmonary arteries of patients with PH (291–293). Bosentan, a dual ERA, lowers PAP and PVR, and improves exercise tolerance in adults with PAH (294). These results can also be extrapolated to children (8,47,264,295,296,297). In children with PAH related to CHD or IPAH, bosentan lowers PAP and PVR, and is well tolerated (295,298). Elevated hepatic aminotransferase levels occur in approximately 11% of adults and 3% of children treated with bosentan. In a 12-week study of children with IPAH or PAH related to CHD, bosentan was well tolerated and lowered PAP and PVR (295). A retrospective study of 86 children on bosentan for a median exposure of 14 months with and without concomitant therapy found that bosentan provided a sustained clinical and hemodynamic improvement and was overall well tolerated, with 2-year survival estimates of 91% (8). Follow-up of these patients at 4 years revealed that the Kaplan-Meier estimate of disease progression in patients while on bosentan was 54% with a survival estimate of 82%. At end of data collection, 25 patients (29%) remained on bosentan. (299). Nevertheless, in a study including both children and adults with PAH and systemic-to-pulmonary shunt, bosentan therapy was shown to produce short-term improvement in WHO functional class and 6MWT distance (167). There was a progressive decline in the beneficial effect of bosentan after 1 year, with a more pronounced decline in the children, who tended to have more severe disease at baseline (167). The safety of bosentan therapy in children with PAH has been recently reported by Beghetti et al. (6). Elevated transaminase levels were reported in 2.7% of children compared with 7.8% of patients aged ≥12 years, and the overall discontinuation rate from bosentan was 14% in children compared with 28% in patients aged ≥12 years. In a Japanese cohort, bosentan pharmacokinetics was not altered by sildenafil (300). Bosentan has been studied in Eisenmenger syndrome in a placebo-controlled trial in patients (see Eisenmenger syndrome). Bosentan was well tolerated and improved exercise capacity and hemodynamics without compromising peripheral oxygen saturation (164). A specific pediatric formulation has been recently approved in Europe (301).

Selective ET_A receptor blockade is also possible using ambrisentan or sitaxsentan, ERAs with high oral bioavailability and a long duration of action, and high specificity for the ET_A receptor. Selective ET_A receptor blockade may benefit patients with PAH by blocking the vasoconstrictor effects of ET_A receptors while maintaining the vasodilator/clearance functions of ET_B receptors. Sitaxsentan given orally for 12 weeks improved exercise capacity and cardiopulmonary hemodynamics in patients with PAH that was idiopathic or related to CTD or CHD (302–304). However, sitaxsentan was removed from the market due to concerns of adverse effects on the liver. Ambrisentan, an ERA that is selective for the ET_A receptor was approved by the FDA in June of 2007. Adults showed significant improvements in 6MWT distance and significant delay in clinical worsening on ambrisentan. The incidence of elevated hepatic aminotransferase levels was 2.8% and was similar to the placebo group (306). In a retrospective study, 38 pediatric PAH patients treated with ambrisentan were evaluated (305). Fifteen of 38 patients were switched from bosentan to ambrisentan. The remaining 23 children were treated with ambrisentan as an add-on therapy due to disease progression. In both transition and add-on cases, mean pulmonary artery pressure significantly improved, and World Health Organization functional class improved in 31% of

patients during the follow-up period (median, range; 20, 4-44 months). Although 5 patients (13%) discontinued ambrisentan due to severe headache, lack of clinical efficacy, or near syncope, no patients had aminotransferase abnormalities and there were no deaths after initiation of ambrisentan during follow-up (305). Recently, monthly liver function testing for ambrisentan was removed from the FDA label, but most centers still perform routine monitoring. Studies in children are underway. A novel dual ERA, macitentan, is currently under study.

PHOSPHODIESTERASE INHIBITORS

Phosphodiesterase type 5 (PDE-5) inhibitors block the degradative action of PDE5 on cyclic GMP in the smooth muscle cells, (307,308), and specific PDE-5 inhibitors, such as sildenafil, (309-314) or tadalafil promote an increase in cGMP levels and thus promote pulmonary vasodilation and remodeling (Fig. 67.13). Sildenafil is as effective a pulmonary vasodilator as inhaled NO and may be preferred because it does not increase pulmonary capillary wedge pressure in patients with an increased wedge pressure at baseline. Sildenafil may also be useful in the setting of inhaled NO therapy withdrawal (315,316,317) in postoperative PH (318), or in the presence of PH related to chronic lung disease (286). Sildenafil was initially studied in 14 children with PAH. During sildenafil therapy, the mean 6MWT distance increased from 278 ± 114 to 443 ± 107 m over 6 months ($p = 0.02$), and at 12 months, the distance walked was 432 ± 156 m ($p = 0.005$). A plateau was reached between 6 and 12 months ($p = 0.48$). Mean PAP and PVR fell (319). In a small study of children with IPAH and PH associated with CHD, sildenafil improved oxyhemoglobin saturation and exercise capacity without significant side effects (313). In children with PAH associated with chronic lung disease, sildenafil has been shown to improve hemodynamics in 88% of patients, was well tolerated, and did not worsen oxyhemoglobin saturation (320). A study of sildenafil in Japanese children has also suggested safety and efficacy (321). In a 16-week, randomized, double-blind study (STARTS-1) the effects of oral sildenafil in pediatric PAH were studied (322). Children ($n = 235$) with PAH (aged 1 to 17 years; ≥ 8 kg) received low-, medium-, or high-dose sildenafil or placebo orally 3 times daily. The primary comparison was percent change in peak oxygen consumption (pVO_2) for the three sildenafil doses combined from baseline to week 16; exercise testing was performed only in children

able to exercise reliably. Secondary endpoints, including mean PAP, PVR, and functional class, were assessed in all enrolled patients, including those unable to reliably exercise. The estimated mean \pm standard error percentage change in pVO_2 for the low, medium and high doses combined versus placebo was $7.7\% \pm 4.0\%$ (95% CI, -0.2% to 15.6% ; $p = 0.056$). Peak VO_2 , functional capacity, mean PAP, and PVR improved with the medium- and high-dose groups compared to placebo, whilst the low dose was ineffective (Fig. 67.18). Upper respiratory tract infections, pyrexia, and vomiting occurred more often with sildenafil than placebo (322). A long-term extension study included children continued on sildenafil monotherapy. At three years, an increase in mortality was noted in the high-dose group and the data safety monitoring board requested to decrease the dose of any child receiving high dose. Deaths in the extension study were related to etiology and baseline disease severity. The majority of deaths occurred in patients with IPAH/FPAH. Of patients who died, most had baseline values above median values for PVRI, mean pulmonary artery pressure, and right atrial pressure. Sildenafil is approved for use in children with PAH in Europe: 10 mg t.i.d. in patients up to 20 kg, and 20 mg t.i.d. in heavier patients, but sildenafil is not approved for children with PAH in the U.S.

Intravenous sildenafil has been shown to potentiate the increase in cGMP in response to NO in children with increased PVR related to CHD or in the postoperative state. Nevertheless, sildenafil infusion has been associated with increased intrapulmonary shunting and augmentation of hypoxemia related to ventilation/perfusion mismatch in the postoperative CHD patient (323,324). However, a recent study of intravenous sildenafil has shown improvement in oxygenation index in PPHN in patients treated with or without inhaled NO (325).

Other PDE-5 inhibitors, such as tadalafil have been recently studied leading to FDA approval in 2009, but studies in children are lacking. Tadalafil is also a selective PDE-5 inhibitor with a longer duration of action than sildenafil. A recent study demonstrated clinical safety and efficacy of tadalafil therapy in 33 pediatric patients with PAH (326). In this study, 29 of 33 patients were switched from sildenafil to tadalafil. The average dose of sildenafil and tadalafil were 3.4 ± 1.1 mg/kg/day and 1.0 ± 0.4 mg/kg/day, respectively. In 14 of 29 children transitioned from sildenafil to tadalafil, repeat cardiac catheterization showed statistically significant improvements in mean pulmonary arterial pressure (53.2 ± 18.3 mmHg versus 47.4 ± 13.7 mmHg, $p < 0.05$) and pulmonary vascular resistance index (12.2 ± 7.0 units \times m 2 versus 10.6 ± 7.2 units \times m 2 , $p < 0.05$) (326). In adults with severe PAH, tadalafil

IX

The Young Adult with Congenital Heart Disease

CHAPTER

68

The Adolescent and Adult with Congenital Heart Disease

Ali N. Zaidi ■ Curt J. Daniels

In the United States, there are approximately 1 million adults with congenital heart disease (CHD), with 20,000 new patients reaching adolescence each year (Fig. 68.1). With earlier pediatric and fetal diagnoses and improved medical, surgical and ICU care, it is now expected that 90% of patients born with CHD will survive to adulthood, and therefore, the number of adult congenital heart disease (ACHD) patients will continue to rise (Fig. 68.2). In fact, it is now estimated that there are more adults living with CHD than children (1) (Fig. 68.3).

Marelli et al. (2) estimated the prevalence of CHD from 1985 to 2000 for children and adults and also found a shift in the population living with CHD to those >18 years of age (Fig. 68.4). Therefore, with further improvements in diagnostic and therapeutic options, the population of adults with CHD will only continue to increase.

Many patients with simple lesions who have undergone total corrective surgery will have few if any hemodynamic residua requiring infrequent evaluation and treatment (e.g., atrial septal defects [ASD], ventricular septal defects [VSDs], patent ductus arteriosus [PDA], and mild pulmonary stenosis).

Patients with more complex lesions, or complications that stem from less complex lesions, such as residual shunts, valvular disease, ventricular dysfunction, and arrhythmias require more frequent evaluation, medical treatment, and consideration for further surgical or catheter-based interventions. As we continue to learn about surgically altered CHDs, some “routine” patients will have previously unrecognized problems. For other adults, surgical approaches of the past and their long-term complications (e.g., D-TGA s/p Mustard or Senning Atrial Repair) will eventually become obsolete and replaced by new complications of present day surgical repair.

The success of pediatric cardiology and CHD surgery is tempered by the long-term complications in adult patients that

may involve every subspecialty within the field of cardiology (Fig. 68.5). By far, the most concerning of these long-term complications is sudden cardiac death (SCD) (3) (Fig. 68.6).

The cardiologist who deals with these patients must therefore be familiar with congenital heart lesions in their uncomplicated state and be aware of appropriate testing and follow-up. Most importantly, they must also provide expert care for both natural and unnatural (surgical) consequences and be qualified to evaluate and treat residual lesions, arrhythmias, and heart failure, and manage high-risk pregnancies in this growing population.

Advanced diagnostic testing with cardiac MRI (CMR) has expanded our ability to evaluate complex CHD with greater clarity, allowing accurate assessment of systemic ventricular function and great vessel anatomy, evaluation of systemic or pulmonary venous baffles and valvular heart disease, and to look for myocardial scar burden with delayed gadolinium techniques. CMR has changed our approach to the ACHD patient shifting the indication for cardiac catheterization from diagnostic to therapeutic. The need for angiography to evaluate ventricular function, aortic arch stenosis or aneurysm, and branch pulmonary artery (PA) stenosis is now rarely necessary, and CMR provides the diagnostic platform for directed catheter-based intervention.

Therefore, ACHD clinics are seeing more patients because of improved survival, are performing more noninvasive diagnostic studies based on the presence of symptoms or using screening tools, and are ultimately treating more patients with catheter-based or surgical intervention. At The Adolescent and Adult Congenital Heart Disease Program at The Nationwide Children’s Hospital and The Ohio State University, we have experienced an exponential rise in all areas of clinical care attesting to the expanding population and the need for ongoing appropriate care for this population (Fig. 68.7).

Figure 68.1. Expanding population of adults with congenital heart disease (CHD) by year.

Figure 68.2. Factors leading to the expanding population of adults with congenital heart disease (CHD).

Figure 68.3. Estimated ratio of pediatric to adult patients with congenital heart disease (CHD).

Figure 68.4. Change in prevalence of congenital heart disease (CHD) from 1985 to 2000 among patients of different age-groups. The highest increase in prevalence has occurred in the 13 to 17 year age group followed by the 18 to 40-year-old group.

Figure 68.6. Risk of sudden cardiac death (SCD) versus years following operative repair for CHD. TOF, tetralogy of Fallot; COA, coarctation of the aorta; AS, aortic stenosis; d-TGA, D-transposition of the great arteries.

Figure 68.7. (A) ACHD clinic, (B) CMR/CT and (C) cardiac catheterization volume since 2000 at The Columbus Ohio Adult Congenital Heart Disease (COACHD) Program at the Nationwide Children's Hospital and The Ohio State University.

Successful ACHD programs employ a multidisciplinary team approach that includes a director having completed specialized training in ACHD cardiology (both adult cardiovascular disease and pediatric cardiology), along with experts in CMR, interventional cardiology, heart failure/cardiac transplant, electrophysiology, cardiothoracic surgery, and midlevel practitioners (advanced practice nurses). There are only a few dedicated ACHD experts currently, due to the need for both CHD experience and adult medicine training.

The following sections review the most common CHD lesions presenting in adulthood with or without prior repair, and the long-term complications, diagnostic workup, and therapeutic options that are deemed necessary.

LEFT-SIDED LESIONS

Bicuspid Aortic Valve

The congenitally bicuspid aortic valve (BAV) is the most common congenital malformation occurring in approximately 2% of the general population (4). It is the most common cause of isolated valvular aortic stenosis (AS) in adults, with a male to female ratio of 3:1 (5). The BAV may be functionally normal with no significant pressure gradient across the valve and with no more than trace valvular aortic regurgitation (AR). However, thickening and focal calcification of the bicuspid valve can be detected as early as in the second decade of life (6). The most common presenting sign or symptom in a young adult is often the detection of a systolic ejection murmur and usually an ejection click. However, depending on the severity of valvular disease, patients with AS or aortic insufficiency may present with exercise intolerance, dyspnea on exertion, or atypical chest pain with the peak incidence of symptoms (angina, syncope, or heart failure) developing with advancing years.

Those without significant AS (usually defined as a gradient <25 mm Hg) and less than mild aortic insufficiency only require regular follow-up. However, over time, the lesion often progresses due to fibrocalcific stenosis with almost 75% of patients requiring eventual surgery (7). The joint study on the Natural History of Congenital Heart Defects followed 473 patients with aortic valve disease at a mean of 20 years (8). Only 20% of those with an initial peak to peak gradient <25 mm Hg at catheterization had a subsequent intervention. However, in those with a gradient >50 mm Hg, arrhythmias, sudden death, endocarditis, syncope, and angina occurred at a rate of 1.2% per year.

The risk factors that lead to the development of AS in patients with BAVs are variable and have been poorly defined, often thought to be related to valvular characteristics. Beppu et al. (9) performed an echocardiographic study evaluating 75 patients (15 to 76 years of age) with a BAV and found that aortic valve sclerosis began around the second decade of life and aortic calcification started in the fourth decade. Aortic valve pressure gradient increased approximately 18 mm Hg each decade, concomitant with valve sclerosis. Patients with anteroposterior (as opposed to right-left) and eccentric (vs. symmetric) valve leaflets had a faster rate of progression with an aortic valve pressure gradient increase averaging 27 mm Hg per decade.

Treatment modalities include percutaneous balloon valvuloplasty that should be considered in a select population with significant aortic stenosis—usually defined as a peak gradient ≥ 60 mm Hg or ≥ 50 mm Hg in a symptomatic patient (10). In a large collaborative registry involving 606 patients, the peak to peak gradient was reduced by a mean of 60% (11). However, this procedure should be considered palliative

and these patients require serial follow-up (12). Pulmonary autograft aortic valve replacement (AVR) (Ross procedure) has a role and for some is the surgical procedure of choice, especially in the adolescent and young adult with significant aortic valve disease. With a successful operation, long-term anticoagulation is not indicated and therefore the patient may not need to be restricted from most activities. The long-term follow-up of this population is promising but particular attention must include assessment of the neo-aortic valve, the neo-aorta, and also the new pulmonary homograft, as it may progressively stenose (13,14). Mid- to long-term results of the Ross procedure have shown excellent results; however, with longer follow-up patients can develop neo-aortic valvular regurgitation and dilation of the neo-aortic root (15,16). Patients with neo-aortic regurgitation and/or neo-aortic root dilation need routine follow-up with serial imaging using echocardiography, CMR, or computed tomography (CT). Whether a patient following the Ross procedure is safe to compete in contact or highly competitive sports is yet to be determined.

BAVs can be associated with other cardiovascular anomalies, the most common of which is coarctation of the aorta (COA). Less common and often previously treated lesions include atrial or VSDs and PDA. Aortic root dilation may develop in some patients with a BAV. Interestingly, some studies provide support to the theory that the BAV is partly a single developmental anomaly affecting the aortic root that eventually leads to aortic root dilation. Two lines of evidence support this theory. First of all, autopsy studies have demonstrated a 5 to 10 times increase in the incidence of aortic dissection compared to patients with trileaflet aortic valves. This occurred without aortic stenosis, aortic coarctation, or hypertension (17,18). Second, Warren et al. (19) in children and Hahn et al. (20) in adults showed that the aortic root was enlarged in patients with a BAV without AS as compared to age- and sex-matched controls. These associations have led to the theory that congenital abnormalities of the aortic valve and the aorta may reflect a common developmental defect. It is also postulated that increased risk of aortic disease in patients with BAVs (including those that function normally) is mediated by coexisting defects in the aortic media by fragmentation of elastic fibers, loss of smooth muscle cells, and increase in collagen (21,22).

Therefore, those with a BAV but without significant aortic valve stenosis or regurgitation require only routine assessment for aortic root enlargement. Echocardiography may be utilized to screen and follow the aortic root, but may not provide adequate imaging beyond the first few centimeters above the sinuses of Valsalva and therefore potentially miss significant enlargement in the distal ascending aorta. CMR as a screening tool is often necessary to evaluate the entire aortic root from the valve annulus to the take off of the great vessels (Fig. 68.8). According to current guidelines, serial evaluation of a patient with a BAV and dilated ascending aorta (>4 cm) with echocardiography, CMR, or CT is recommended on a yearly basis, and first-degree relatives of all patients with a BAV should be screened with echocardiography (23). Since 2007, the need for antibiotic prophylaxis for patients with BAVs prior to dental or surgical procedures is not considered necessary (24).

Surgery is recommended to repair the aortic root or replace the ascending aorta in patients with BAVs if the diameter of the aortic root or ascending aorta is >5 cm, if the rate of increase in diameter is 0.5 cm per year or more, or if patients are undergoing AVR due to severe AS or AR, when the diameter of the aortic root or ascending aorta exceeds 4.5 cm (23). Borger et al. (24) found that the 15-year freedom from aortic root complications (replacement, dissection) following AVR was 86%, 81%, and 43% for aortic diameters of <40 mm, 41 to 44 mm, and >45 mm, respectively at the time of AVR.

Figure 68.8. Cardiovascular magnetic resonance imaging (CMR). A: 26-year-old with BAV with no aortic stenosis/aortic valve insufficiency, CMR demonstrates aortic root enlargement measuring 4.7 cm at the widest diameter mid ascending aorta. B: A 32-year-old with BAV, mild AS, and large ascending aortic aneurysm measuring 5.2 cm with the widest diameter just proximal to the take off of the right innominate artery. Echocardiographic maximal diameter just above sinuses of valsalva was 4.0 cm, therefore underestimating the maximal diameter of the ascending aorta.

Aortic Valve Regurgitation

Aortic valve regurgitation is usually a manifestation of a congenitally abnormal aortic valve, subaortic obstruction damaging the aortic valve, aortic cusp prolapse through a supulmonic VSD, or aortic root dilation from connective tissue disorder. For most, chronic aortic valve regurgitation is well tolerated for a number of years, with slow progression but can ultimately lead to left ventricular dilation and dysfunction. Such patients are often asymptomatic for decades, until they have symptoms suggestive of left heart failure (dyspnea with exertion, angina, or syncope). The volume load that affects the left ventricle (LV) leads to a series of compensatory myocardial remodeling that lead to left ventricular dilation. Often, these changes can be reversed using appropriate pharmacologic therapy; however, ultimately patients with significant aortic valve regurgitation and dilated LVs may require AVR. Patients with severe AR can be treated with vasodilator therapies to alleviate the volume load on the LV (when AVR is not recommended) or to improve the hemodynamic profile and provide symptomatic relief for patients with severe heart failure and severe LV dysfunction (23).

The appropriate timing of AVR for aortic valve regurgitation is partially based on the development of symptoms. Symptomatic adults (with angina, syncope, or dyspnea with exertion) with chronic severe AR should undergo AVR. Asymptomatic patients with chronic severe AR with LV systolic dysfunction (ejection fraction [EF] <0.50) or with progressive LV enlargement (end-diastolic dimension greater than four standard deviations above normal) should receive aortic valve repair or replacement (23).

The presence of LV systolic dysfunction (left ventricular ejection fraction <0.5) indicates that the patient may be entering a decompensated stage. Such patients should not only undergo intense medical treatment including the use of vasodilators and diuretics to eliminate the congestive state but should also undergo a thorough evaluation and be considered for AVR.

Subaortic Stenosis

Subvalvar AS encompasses a variety of lesions that can occur alone or in combination. These include a thin membrane (the most common lesion), thick fibromuscular ridge, diffuse tunnel-like obstruction, abnormal mitral valve attachments, and occasionally, accessory endocardial cushion tissue.

In the majority of patients, obstruction is caused by a discrete membrane or a thick fibromuscular ridge that is attached to the ventricular septum or completely encircles the left ventricular outflow tract. Diffuse, “tunnel-like” narrowing of the left ventricular outflow tract is rare and is characterized by marked myocardial hypertrophy and, often, aortic annular hypoplasia.

Patients with mild to moderate obstruction often remain asymptomatic for several years and are often not identified until later in life. Significant subaortic obstruction is associated with left ventricular hypertrophy (LVH), and often with aortic valvular regurgitation leading to operative repair. In contrast to valvar AS, subvalvar AS does not respond to balloon dilation. Definitive therapy consists of surgical correction using simple membrane removal, extensive ring resection with or without myomectomy, or the Konno procedure. Patients with discrete membrane or fibromuscular ridge usually would have undergone surgery by adulthood; however, these lesions have a tendency for regrowth and concomitant aortic valve disease (25). A large retrospective study of 75 patients after surgical resection found a recurrence rate of 16% at 5 years and 30% at 10 years. A higher preoperative gradient (>40 mm Hg), higher postoperative gradient (>10 mm Hg), and younger age at surgery were predictors for recurrence (26). Additionally, the need for aortic valve repair and the progressive aortic insufficiency occurred less often in those with a lower preoperative gradient. This finding has led some to recommend early repair of fixed subaortic obstruction prior to the development of high-gradient or aortic valve disease (26).

Lupinetti et al. was able to demonstrate a significantly lower recurrence of subaortic obstruction requiring reoperation when membrane excision was combined with myectomy as opposed to membrane excision alone (4% vs. 25% over a mean of 4.5 and 5.2 years, respectively). However, there was a slightly higher incidence of postoperative heart block in the myectomy group (27).

With or without surgical intervention, AR may develop many years after the initial diagnosis. Therefore, patients with subaortic stenosis should have periodic evaluation. Unoperated adults with mild to moderate gradients without significant LVH and trace AR should be followed periodically. Surgery for prevention of AR in such patients is not indicated at this time; however, the presence of AR is frequently used as a surrogate marker for surgical intervention.

Coarctation of the Aorta

COA is usually a postoperative concern in adults. Previously undiagnosed adults with native coarctation are rare. Most adult patients are asymptomatic, unless they have severe hypertension leading to headaches, epistaxis, heart failure, and/or aortic dissection.

Unfortunately, despite adequate childhood surgery, patients are at risk for several concern-causing long-term complications:

1. Systemic hypertension
2. Recoarctation
3. Aortic aneurysm and dissection
4. SCD

A long-term follow-up study of patients repaired in childhood or adolescence demonstrated a significantly reduced long-term survival—mean age of death being 38 years (28). Patients died from, in decreasing order, coronary artery disease, congestive heart failure, sudden death, cerebral vascular accidents, and ruptured aortic aneurysms. Silka et al. (3) found the risk of SCD following COA repair to be 25 times greater than expected 20 years from repair.

Systemic Hypertension

Systemic hypertension is one of the major long-term problems following repair of COA. Although the blood pressure (BP) typically falls after successful repair, persistent or recurrent hypertension and disproportionate systolic hypertension with exercise are not uncommon.

Multiple studies have found a significant incidence of systemic hypertension either at rest or with exercise following repair (29–32). When combining resting BP, ambulatory BP monitoring, and exercise testing, systemic hypertension has been reported in as many as 70% of patients following coarctation repair (33). Hypertension may occur irrespective of the age at surgery or the presence of a residual gradient. Patients who had delayed initial repair often have residual hypertension despite surgical or transcatheter intervention. When hypertension is detected at rest, recoarctation must be excluded by physical exam (brachial/femoral pulse delay, arm/leg BP gradient), Doppler echocardiography, and/or CMR or Cardiac CT imaging. Recoarctation should be evaluated for transcatheter therapy (stent, angioplasty)—see ACHD interventional therapy section.

If there is no evidence of recoarctation, then medical management for hypertension is indicated. Once resting BP is normal, assessment of activity-related hypertension is performed with a 24-hour ambulatory BP monitor or in athletes, an exercise study should be done to determine peak systolic BP at maximal exercise.

Figure 68.9. A 39-year-old with COA s/p end-to-end anastomosis presents with hypertension and found to have recoarctation, (see arrow) subsequently relieved with transcatheter stent therapy.

Recoarctation

Recurrent recoarctation refers to restenosis after an initially successful intervention. Often the major findings that suggest that a patient has developed recoarctation are resting hypertension and headaches, though some patients can be asymptomatic. Recoarctation occur less often in older patients (34,35). Recoarctation can be based on anatomic narrowing, arm/leg BP gradient, evidence of hypertension, or a combination of these factors (Fig. 68.9). Most patients with recoarctation will undergo transcatheter therapy to relieve the aortic obstruction (see section ACHD interventional therapy).

Discrete coarctation in older children and adults is treated with percutaneous balloon angioplasty, often with stent therapy (36). Indications for percutaneous interventions for recurrent discrete coarctation include a peak to peak gradient of at least 20 mm Hg (36). Eicken et al. (37) reported that despite successful stent therapy, the patient may still demonstrate systemic hypertension requiring medical therapy once again attesting to the intrinsic abnormality associated with COA.

Aortic Aneurysm/Pseudoaneurysm

An aortic aneurysm may develop following surgery or balloon dilation of native coarctation, typically at the site of prior repair. Development of aortic aneurysm and rupture may occur years after successful repair of COA (38–41). This finding can occur without recurrent coarctation and despite relief of systemic hypertension (Fig. 68.10). For the majority of patients, aneurysm repair requires surgical intervention with resection of the aneurysm and graft placement. Unfortunately, there are no criteria to guide the timing of aortic aneurysm repair in this population.

Pseudoaneurysms at the COA repair site are an area of weakening with outpouching of the adventitial thin layer of the aorta usually along the suture line. Pseudoaneurysms are at a higher risk for rupture and should be considered

Figure 68.10. A: A 28-year-old asymptomatic patient s/p patch aortoplasty repair for COA presented for routine screening. Cardiac CT demonstrated a large aortic aneurysm at the repair site. B: A 35-year-old patient s/p end—end anastomosis for COA presented with hypertension and back pain. Cardiovascular magnetic resonance imaging revealed recoarctation with aneurysm at the site of repair. C: A 38-year-old patient with end-to-end anastomosis COA repair presents for routine screening and found to have an aneurysm at repair site measuring 4.2 cm.

for repair at the time of diagnosis. Either surgical repair or in select cases, excluding the aneurysm with a covered stent should be employed to remove the risk of pseudoaneurysm rupture (Fig. 68.11).

Although risk factors for postrepair aneurysms have been identified, including a later age at initial repair and the use of patch angioplasty, there are no clear risk factors for the higher incidence of hypertension and aortic dissection following coarctation repair. However, a growing body of evidence demonstrates that there is an intrinsic abnormality of aortic

function that persists despite adequate repair (42). Patients with repaired coarctation can rarely also develop aneurysms of the ascending aorta, which are often associated with BAVs (43–46). A stiff or less distensible aorta has been described with essential hypertension, coronary artery disease, and Marfan syndrome and may be the underlying mechanism contributing to the late abnormalities associated with repaired COA (43).

Documenting the type of repair performed is important in the evaluation of this population. Most underwent patch aortoplasty, resection of the coarctation with end-to-end

Figure 68.11. Aortogram from a 26-year-old patient with COA s/p end-to-end anastomosis found upon routine screening to have a small pseudoaneurysm and recoarctation at the repair site. The aneurysm was excluded and the obstruction relieved with a covered stent.

anastomosis, or subclavian flap repair. However, a small percent may have undergone bypass tube grafting around the coarctation segment. A clear understanding of the type of repair will aid in the diagnosis of complications and help guide timing as to when follow-up studies are necessary (Fig. 68.12). Therrien et al. (47) demonstrated that the most cost-effective

Figure 68.12. Cardiac CT in a 26-year-old patient with COA s/p ascending aorta to descending aorta tube graft.

evaluation for adults with repaired COA includes a clinical visit (thorough history and physical examination) and CMR to rule out aortic aneurysm and recoarctation.

Adult patients with previous coarctation repair should be followed serially for evidence of hypertension, both at rest and with ambulatory monitoring, and should be carefully assessed for recoarctation, aortic aneurysms, aortopathy, and progressive valvular disease especially in those with concomitant aortic or mitral valve abnormalities.

LEFT-TO-RIGHT SHUNTING LESIONS

Adults may present either with repaired or unrepaired hemodynamically significant shunt lesions including VSDs, atrioventricular septal defects (AVSDs), ASDs, PDA, in rare cases aorticopulmonary window, and arteriovenous (including coronary) fistulae. Those with shunt lesions repaired at a young age (VSD, AVSD, PDA < 1 year) are unlikely to develop pulmonary vascular disease. Large shunts either left unrepaired as a child or found incidentally as an adult will inevitably lead to elevated pulmonary vascular resistance and Eisenmenger syndrome (ES).

Ventricular and Atrioventricular Septal Defects

Adult patients with VSDs or AVSDs associated with high pulmonary resistance (especially if operated later than 1 year of age) can develop increasing pulmonary vascular obstructive disease (PVOD) (48–51). Associated concerns include residual shunts, aortic valve regurgitation, arrhythmias, including complete heart block requiring a pacemaker, PA deformity or acquired pulmonary valve stenosis (PVS) from previously placed pulmonary arterial bands, and residual atrioventricular (AV) valve regurgitation in the AVSD group. The varied constellation of symptoms can often make their clinical presentation, natural history, and treatment quite variable and make treatment options challenging.

Many patients who have a VSD do not undergo repair because the VSD is anatomically small, closing, or hemodynamically insignificant. This applies particularly to perimembranous defects where septal aneurysmal tissue can partially occlude the defect and to some smaller muscular defects. On the other hand, false security might exist when a subpulmonic defect seems to be getting smaller. In these patients, an aortic cusp can prolapse and partially or completely occlude the defect. In these patients, early operation is necessary to help protect the integrity of aortic valve coaptation.

Though it is rare to find an adult patient who would benefit from isolated VSD closure, thorough clinical, echocardiographic assessment and at times invasive hemodynamic evaluation are important in the evaluation of these patients to determine the most appropriate timing of surgical or percutaneous VSD repair, to prevent the development of irreversible PVOD, preserve the integrity of the aortic valve, and protect LV size and function. In unrepaired adults, either the VSD is small and restrictive and therefore closure would not be indicated, or at the other extreme, the defect is large enough to have caused PVOD and closure would subsequently be considered harmful.

Though surgical repair is first line for most VSDs, transcatheter device VSD closure is a treatment option for isolated uncomplicated muscular VSDs and for certain membranous VSDs, but only in very selected patients with suitable anatomy. The technical success rate of transcatheter closure of selected muscular and membranous VSDs is high and the mortality rate is low (52). Hijazi et al. reported 10-year results of percutaneous closure in adult congenital and acquired (non-post-infarct) VSDs using different types of Amplatzer occluder devices. The patients ranged in age from 18 to 84 years with a median age of

34 years. Indications for closure included symptoms related to significant shunt (dyspnea on exertion), unexplained deterioration of LV function and/or LV dilation, recurrent endocarditis, and concerns for pulmonary hypertension (PH). They showed that the procedure was both safe (two minor procedural complications) and very effective in eliminating intracardiac shunts, showing improvement in LV size after closure (53).

Long-term survival is excellent for patients with small restrictive VSD, normal ventricular function, and normal PA pressures but is limited for those with Eisenmenger complex.

Atrial Septal Defect

ASDs are the most common congenital lesion in adults after BAV. Although the defect is often asymptomatic until adulthood, potential complications of an undetected ASD include right ventricular failure, atrial arrhythmias, paradoxical embolization leading to a cerebrovascular accident or transient ischemic attacks, cerebral abscess, and PH that can become irreversible and lead to right-to-left shunting (ES). Most smaller ASDs close spontaneously in infants; however, spontaneous closure is unusual in older children and adults. Patients with ASDs are often operated before adulthood. Rarely, patients will go undetected until a high school sports physical examination or following an incidental chest film that is interpreted as abnormal. Exercise intolerance, fatigue, dyspnea, overt heart failure, and paradoxical embolization are manifestations of symptomatic ASDs in adults that warrant defect closure. Most patients do well in the long term after successful surgical closure and remain symptom free, though rare atrial arrhythmias or sick sinus syndrome can occur (54).

Murphy et al. (55) demonstrated that the age at operation and the PA pressure influences survival after ASD repair. Patients repaired <25 years of age have similar long-term survival compared to controls. However, patients ≥25 years old and those with PA systolic pressure ≥40 mm Hg at repair have a lower long-term survival apparently due to late cardiac failure, stroke, and atrial fibrillation (Fig. 68.13). The

postoperative ASD patients should be followed, albeit infrequently, with periodic examinations, electrocardiography, and occasional 24-hour ambulatory monitoring.

Percutaneous device closure is an alternative to surgical closure in patients with ostium secundum ASDs that have appropriate anatomic characteristics. The United States Food and Drug Administration's Center for Devices and Radiological Health has approved two devices for percutaneous ASD closure (56,57): the Amplatzer Septal Occluder and the CardioSEAL Septal Occlusion System. The indications for transcatheter device closure are the same as surgical closure (see interventional cardiac catheterization, Chapter 13) except that device closure with Amplatzer atrial septal occluder (ASO) is only indicated for secundum ASDs up to a maximum device size of 38 mm. Patients with sinus venosus or primum ASDs and any patient with an anomalous pulmonary venous return should have surgical repair.

Congenital Heart Disease, Pulmonary Hypertension, and Eisenmenger Syndrome

Significant left-to-right shunts unrepaired or those repaired at a later age may develop PH. Defects or complexes lesions at risk to develop PH include

1. L-R shunting defects—ASD, VSD, AVSD, PDA AP window
2. Single ventricle complexes—double-outlet right ventricle, double-inlet left ventricle
3. Transposition of the great arteries
4. Truncus arteriosus

In a large ACHD registry of over 5,000 patients from the Netherlands, the overall incidence of PH was 4.2%, 6% in those with only a septal defect, and 10% in those with a high-risk lesion for PH (categories above) (58,59) (Fig. 68.14). Of those with a septal defect and PH, 58% met the definition of ES. VSD was the most common diagnosis in the group with septal defects and PH; however, AVSD had the highest prevalence at 41% (Fig. 68.15).

ASD Long-Term Survival; Age and Main Pulmonary Artery Pressure at Operation

Figure 68.13. Survival curves for atrial septal defect (ASD) patients based upon age at surgical repair (≤ or >24 years of age) and pulmonary artery (PA) systolic pressure at the time of repair (< or ≥40 mm Hg). Survival was significantly diminished only with a combination of age 24 years and PA systolic pressure >40 mm Hg (Eicken A, Pensl U, Sebening W, et al. The fate of systemic blood pressure in patients after effectively stented coarctation. *Eur Heart J* 2006;27:1100–1105).

Prevalence of Pulmonary Hypertension in the Main Diagnostic Groups

Figure 68.14. Prevalence of pulmonary hypertension (PH) in the main diagnostic categories from the CONCOR project. ASD, atrial septal defect; VSD, ventricular septal defect; ASD I, Primum atrial septal defect; AVSD, atrioventricular septal defect; TOF, tetralogy of Fallot; CoA, coarctation of the aorta; DORV, double-outlet right ventricle. (From Vander Velde ET, Vriend JW, Mannens MM, et al. CONCOR, an initiative towards a national registry and DNA-bank of patients with congenital heart disease in the Netherlands: Rationale, design, and first results. *Eur J Epidemiol* 2005;20:549–557, with permission.)

Total Number of Patients ($n = 1824$) per Type of Septal Defect in the CONCOR Registry

Figure 68.15. Total number of patients from the CONCOR project with septal defects and those with PH. VSD is the most common septal defect with PH and AVSD has the highest prevalence. VSD, ventricular septal defect; ASD II, secundum atrial septal defect; ASD I, primum atrial septal defect; AVSD, atrio-ventricular septal defect. (From Duffels MG, Engelfriet PM, Berger RM, et al. Pulmonary arterial hypertension in congenital heart disease: an epidemiologic perspective from a Dutch registry. *Int J Cardiol* 2006;120:198–204, with permission.)

Eisenmenger Syndrome

ES consists of systemic-to-pulmonary cardiovascular communication, pulmonary arterial disease, and cyanosis. The development of pulmonary arterial disease is a consequence of increased pulmonary blood flow and pressure and requires exclusion of other causes of PH. The diagnosis requires the presence of underlying CHD, though in some cases the diagnosis is not established until adulthood. With the advent and subsequent advancement of surgical management of CHD, the incidence of ES has declined, though it is not negligible. The overall incidence of ES is not known.

In the Netherlands study, 1% of all of the patients registered through their ACHD clinic and 58% of those with a septal defect and PH had ES (55). The development of ES is based upon the size and location of the left-to-right shunt. From the second natural history study of patients with VSD, 3% of those with a small to moderate defect (≤ 1.5 cm in diameter) will develop ES. However, with a large VSD (>1.5 cm), nearly 50% will develop ES (60). From the time of PH diagnosis, ES survival is longer than those with the idiopathic PH and patients commonly survive into the third or fourth decade of life with ES. Patients with ES carry a survival rate of 80% at 10 years, 77% at 15 years, and 42% at 25 years. Poorer survival has been associated with syncope, elevated right heart filling pressures, and lower systemic saturations ($<85\%$) (61–63).

ES patients are at risk for multiple medical problems including polycythemia, coagulopathy, especially platelet consumption, brain abscess, cerebral microemboli, hemoptysis, gout, and renal dysfunction (64). These patients should be routinely seen by centers with CHD–pulmonary artery hypertension (PAH)-trained physicians. The evaluation should include comprehensive assessment of their functional capacity, measurement of their hemoglobin, platelet count, iron studies, creatinine, and uric acid. Digital oximetry, both with and without supplemental oxygen therapy and oxygen-responsive hypoxemia should be investigated and they warrant expedited evaluation and treatment of underlying arrhythmias (65).

Other situations that are associated with a markedly increased risk in patients with ES include pregnancy, volume depletion, isometric exercise, high altitude (including air travel), and endocardial pacing. Meticulous care of intravenous

(IV) lines is required to avoid the risk of air emboli. Pregnancy in patients with ES is associated with significant morbidity and mortality and is contraindicated. The reported rate of maternal mortality in patients with ES is between 30% and 50%, with pregnancy continuing to be prohibitive in such patients despite the advances in medical therapies (6666). Gatzoulis et al. (67) reported that the overall maternal mortality was lower compared with data from a previous era (25% vs. 38%), with 17% mortality in patients with idiopathic PAH, 28% in those with CHD–PAH, and 33% in patients with other causes for PH.

Symptomatic patients with PVOD may benefit from phlebotomy and non-red cell colloid replacement. Patients should be carefully monitored during the procedure. This procedure repeated periodically carries the risk of hypotension and even death, especially if fluid shifts during the phlebotomy procedure are abrupt. Therefore, phlebotomy should only be approached as a therapy when there are significant symptoms felt to clearly be due to polycythemia and hyperviscosity rather than polycythemia alone. Symptoms include worsening dyspnea and hemoptysis. In select patients, presurgical phlebotomy may be beneficial to reduce bleeding diathesis risk (64).

Particular care must be taken not to deplete the iron stores in these patients. A patient with Eisenmenger complex who has several phlebotomies and has a hemoglobin of 18 g/dL, but who has microcytosis has iron deficiency polycythemia. These patients are at higher risk for cerebral vascular accidents. The Mayo clinic reviewed the course of 162 cyanotic CHD patients ≥ 18 years of age over an 8-year period and found that 29 cerebrovascular events had occurred in 22 patients (13.6%) (68). Risk factors for the development of a cerebrovascular event included hypertension, atrial fibrillation, a history of phlebotomy, and microcytosis. Microcytosis was the strongest predictor for a cerebrovascular event. Judicious iron replacement with frequent monitoring of the hemoglobin level and mean corpuscular volume is necessary.

In the last decade, medical therapy for ES has become an important consideration to improve exercise capacity and as a bridge to lung or heart/lung transplantation. Bosentan (a dual endothelin receptor antagonist), epoprostenol (a prostacyclin [PC]), and sildenafil (a phosphodiesterase-5 inhibitor) have been evaluated in limited numbers of patients with ES. In the only randomized controlled trial dedicated to end-stage PAH–CHD, bosentan significantly reduced pulmonary vascular resistance and significantly increased 6-minute walk distance without compromising peripheral oxygen saturation in patients with ES. These data suggest that targeted therapies are beneficial in the PAH–CHD population, and warrant further research (69). More recently, Zuckerman et al. (70) showed that in a small cohort of patients with ES, ambrisentan (endothelin receptor antagonist) was safe and was associated with increasing exercise capacity.

In a short-term study, Fernandes et al. demonstrated significant improvement in exercise capacity and hemodynamics with IV PC use. ES patients ($n = 8$, mean age 37 years) underwent hemodynamic assessment and 6-minute walk test at baseline and at 3 months following initiation of IV PC. The median pulmonary valve replacement (PVR) for the group decreased from 41 to 21 U/m², $Qp:Qs$ ratio shifted more leftward from 0.55 to 0.75:1, systemic saturation improved from 69% to 85%, and the 6-minute walk distance improved from 68 to 375 yards (Fig. 68.16) (71). Galie et al. (72) randomized 54 ES patients to either placebo ($n = 17$) or to the endothelin receptor antagonist Bosentan ($n = 37$). After 16 weeks, Bosentan patients demonstrated a significant reduction in PVR and mean PA pressure and an improvement in exercise capacity compared to the placebo patients. Adriaenssens and colleagues found a significant delay in need for transplant when patients were treated with advanced medical therapy (IV PC or endothelin receptor antagonist) compared to those

Figure 68.16. Eisenmenger patients who underwent baseline and 3-month follow-up 6-minute walk test after initiation of IV PC therapy. There was a significant improvement in exercise capacity by 6-minute walk test.

without PH-specific medications, 7.8 ± 1.0 versus 3.4 ± 0.9 years, respectively (Fig. 68.17) (73).

Therefore, ES patients should be considered for PH-specific medications either to improve exercise tolerance or as a bridge to transplant. Whether survival is improved with PH-specific medication is more difficult to determine.

Heart and lung transplantation or lung transplantation with intracardiac repair are treatment options in Eisenmenger patients. Transplantation should be reserved for severely symptomatic patients (74,75). The survival of ES patients who undergo lung or heart/lung transplantation in some studies was less than that of idiopathic PH, but in other studies the survival was similar to those with idiopathic PH or pulmonary fibrosis. In general, the 5-year survival is approximately 55%, 10 year 35%, and 15 year 20% (76,77).

Therefore, there are options for the ES patient that were not previously available or readily considered. General guidelines include the following:

1. Confirm the anatomy and determine that no surgical intervention is necessary, for example, anecdotal cases exist where an adult with tetralogy of Fallot (TOF) was misdiagnosed as having ES should be completely repaired.

Figure 68.17. Kaplan-Meier curves for waiting on transplant list or death versus time on either standard medical therapy or advanced therapy with PC or endothelin receptor antagonist. Log rank test $p = 0.0062$.

2. Maintain adequate hydration.
3. Provide oxygen therapy at night especially in case of documented worsening nocturnal systemic saturations.
4. Phelbotomy only in select cases where hyperviscosity is the etiology of the symptoms. Replace blood volume with adequate intravenous colloid solution in a monitored environment.
5. Discuss and recommend permanent sterilization in women.
6. Consider PH-specific medications (e.g., endothelin receptor antagonists, IV PC therapies), particularly for those with declining functional status.
7. In select patients consider lung or heart/lung transplantation.

Patent Ductus Arteriosus

PDA is one of the few lesions that can be considered cured by operation, and unless rare complications of “recanalization” have occurred, these patients can be discharged from further cardiac reevaluation.

PDA closure is recommended for patients with a significant left-to-right shunt who are symptomatic, have evidence of left-sided volume overload (i.e., left atrial or ventricular enlargement), or have reversible pulmonary arterial hypertension (PAH) (66,78). PDA closure is not recommended for patients with severe and/or irreversible PAH, since closure in such patients does not improve survival and often right-to-left shunting is needed to maintain adequate cardiac output, especially during episodes of increased pulmonary vascular resistance (78). Most clinically relevant PDAs are closed (pharmacologically, surgically, or via percutaneous intervention) during either infancy or early childhood. The rare patient who is not diagnosed with a PDA until adulthood should have preoperative hemodynamic cardiac catheterization before being considered for closure. Some may have low-flow shunts due to PVOD, and this must be established before treatment.

In the older patient, an additional consideration is the potential for significant pulmonary vascular disease and PAH. However, it is not always clear which patient with PAH will benefit from PDA occlusion. Careful consideration for PDA closure must be given to patients with PAH. Patients with documented patent ductus arteriosus with pulmonary vascular resistance >6 Wood units/ m^2 when breathing 100% oxygen are usually not considered suitable candidates for correction of their shunt (78).

The anatomy of PDA in the adult is remarkable for the presence of calcification and general tissue friability in the area of the aortic isthmus and PA, which makes surgical manipulation in the adult more hazardous than in the child. Thus, surgery even for a small ductus in the adult, carries a serious risk because the calcified ductal wall can tear during ligation (66,79). Thus, these procedures should take place in a center where an experienced surgeon and team can deal with such patients. Adults with PDA are better suited for percutaneous closure with either an occlusion device or coils because of high success and few complications, and is now considered to be the treatment of choice, especially in the patient with comorbidities (80).

OTHER VALVE ABNORMALITIES

Mitral Valve Prolapse

Mitral valve prolapse (MVP) is the most common cause of primary mitral regurgitation (MR) in developed countries. Since symptoms are nonspecific, the diagnosis of MVP is usually suspected on physical examination and confirmed by echocardiography. MVP is often encountered for the first time in adolescence or early adulthood. Because it is a clinical diagnosis with Doppler echocardiographic corroboration (if necessary), careful dynamic

auscultation of the patient in various positions, especially when standing after squatting, is important (see Chapter 5).

MVP has had many names, including click/murmur syndrome, myxomatous mitral valve disease, floppy valve syndrome, and Barlow's syndrome. It is classified as primary, secondary, or functional based upon the anatomic or physiologic defects responsible for the abnormal leaflet motion. If the prolapse valve is not due to a floppy valve in association with a connective tissue disorder, then the degree of prolapse usually does not progress until the patient is older, with most patients remaining asymptomatic. MVP can be associated with chest pain, palpitations, dizziness, numbness, or tingling but these symptoms are usually benign and only require careful history, examination, electrocardiography, and occasionally 24-hour ambulatory monitoring (81). Reinforcement by inquiry may make the patient more symptomatic than is necessary. However, even asymptomatic patients, especially young women, can suffer sudden death when no other pathologically proven cause can be found (82,83). The exact incidence of sudden death associated with MVP is unknown. Furthermore, since atrial and ventricular arrhythmias are common in the general population, it is not clearly established that the incidence of arrhythmias and SCD are in fact increased in patients with MVP. It has been postulated that the incidence of arrhythmias may be higher in patients with MVP who have at least moderate MR (84).

It is important to always perform dynamic auscultation. The classic murmur of MVP is accentuated by standing and Valsalva maneuver (earlier systolic click and longer murmur) and diminished with squatting (later systolic click(s) and shorter murmur).

The symptomatic relief of patients with MVP may require both general and pharmacologic measures. Reassurance about the benign nature of the disorder is often adequate to reduce the severity of symptoms in many patients. Many patients also appear to benefit from a change in lifestyle, including aerobic exercise training, the avoidance of stimulants (caffeine), alcohol, undue fatigue, and a reduction in stress. Beta-blockers may be helpful in patients with MVP who present with hyperadrenergic state including tachycardia, palpitations, or nervousness but there have been no large-scale randomized trials to prove their benefit in this cohort of patients (85).

Though most patients do not need surgical therapies, MVP associated with severe MR can be treated with repair or surgical replacement of the mitral valve. Repair of the mitral valve is always preferable to replacement and should be performed by surgeons who are skilled in the procedure (22).

Pulmonary Valve Stenosis

Almost all cases of valvular pulmonic stenosis are congenital in origin, and most cases occur as an isolated lesion. Acquired cases are encountered less commonly but may be caused by the carcinoid syndrome, rheumatic fever (in which case pulmonic stenosis is always associated with other valve abnormalities), or stenosis of a bioprosthetic valve or valved conduit. Mild or moderate PVS is not a progressively obstructive lesion. Most patients who have had severe PVS would have had either balloon valvuloplasty or operation and should have little to no outflow obstruction by the time they reach adolescence.

Earing and colleagues at the Mayo clinic reviewed the long-term outcome after surgical repair for PVS (86). Fifty-three patients (mean age at follow-up 43 ± 15 years) who underwent surgical treatment for PVS from 1951 to 1982 were reviewed 33 years (range 18 to 51 years) later. At follow-up, 53% had reintervention with PVR for pulmonary insufficiency (PI) being the most common operation. Atrial and ventricular arrhythmias were common (38%).

The rare undetected or untreated adolescent or adult patient with significant PVS may still require intervention. The

initial diagnostic modality of choice remains a transthoracic echocardiogram in patients with isolated pulmonary valvar stenosis. The role of diagnostic cardiac catheterization is now only indicated in patients if the Doppler peak jet velocity is >3 m/s (estimated peak gradient >36 mm Hg), and balloon dilation can be performed if indicated (22). The high success and low complication rates, along with favorable long-term hemodynamic and clinical results, have resulted in pulmonary balloon valvotomy becoming the treatment of choice for patients with moderate to severe pulmonic stenosis. It is recommended in symptomatic patients with a right ventricle (RV)-to-PA gradient >30 mm Hg, or in asymptomatic patients with a RV-to-PA gradient greater than 40 mm Hg at catheterization (22). Pulmonary balloon valvuloplasty is effective with good mid-term results similar to surgical valvulotomy (see Chapters 13 and 40). Whether treated or not, those with right ventricular outflow gradients (and normal cardiac output) <50 mm Hg can expect a normal lifespan and no symptoms (87,88).

Cyanotic Congenital Defects

Adults with CHD anatomy associated with cyanosis would nearly always have had some type of prior operation. These operations may have been palliative, such as systemic artery-PA shunts or systemic vein-PA shunts, or they might have undergone definitive procedures, such as closure of VSD and opening of the right ventricular outflow as in TOF.

Although many patients who had systemic-to-PA anastomoses have sufficient pulmonary blood flow to achieve reasonable systemic arterial oxygen saturation, some patients with palliative shunts have developed PVOD, possibly related to a high-flow-high-pressure stimulus. This particularly applies to those who had the now-seldom-used Potts or Waterston central shunts. The latter was frequently associated with distortion and even obstruction of the right PA at the site of anastomosis (Fig. 68.18). These patients still have obligatory intracardiac right-to-left shunting, and air or clots

Figure 68.18. Right PA angiogram in a 26-year-old patient with rTOF s/p palliative Waterston shunt. Angiogram demonstrates discrete right PA stenosis (arrow) and hypoplastic secondary and tertiary branch vessels. Patient underwent successful angioplasty and stent therapy.

from intravenously placed lines can embolize paradoxically, leading to brain, renal, or cardiac infarction. Additionally, the group of patients with cyanotic CHD and palliative systemic artery-PA shunts is at the highest risk for endocarditis (89).

Tetralogy of Fallot

The majority of young adults with TOF would have undergone complete repair. It is important during the patient evaluation to obtain a detailed history of prior surgical procedures. Depending on the degree of pulmonary outflow obstruction, size of the pulmonary arteries, presence of branch pulmonary stenosis, and coronary anatomy, a variety of techniques might have been utilized to complete the repair. A prior systemic to PA shunt (i.e., Blalock-Thomas-Taussig, Waterston, Potts) has the potential to cause elevated pulmonary vascular resistance and distortion of the branch pulmonary arteries (Fig. 68.18). This appears especially true for the patients with a prior Waterston shunt or Potts operation. Murphy et al. (90) found a significant decrease in survival after complete repair for patients with a prior Waterston shunt or Potts operation compared to those with Blalock-Thomas-Taussig shunt. This occurred presumably from progressive PVOD as a consequence of high pulmonary blood flow from a larger size shunt. Improving surgical techniques have now made a single intracardiac repair the procedure of choice in most centers rather than a staged approach.

Patients with TOF and pulmonary valve atresia, or anomalous left anterior descending coronary artery from the right coronary artery would have had a prosthetic or homograft conduit, with or without a valve placed between the RV and the PA. These conduits can develop endothelial overgrowth and the valves can stiffen, both causing progressive obstruction to the neo-right ventricular outflow area (91,92). These patients should be periodically reevaluated for development of obstruction that may be treated by balloon dilation transcatheter valve replacement or by operative conduit replacement.

The most typical adult with TOF would have undergone complete repair (rTOF), with VSD patch closure, pulmonary valvectomy, transannular patch, and possibly subpulmonic infundibulectomy. Long-term complications of surgically repaired patients with TOF include

- chronic pulmonary regurgitation leading to right ventricular enlargement,
- residual right ventricular outflow tract (RVOT) obstruction,
- RV wall motion abnormalities with progressive RV dysfunction,
- supraventricular and ventricular arrhythmias including ventricular tachycardia (VT) (usually monomorphic) and
- the risk for SCD

Both atrial and ventricular tachyarrhythmias are common after repair of TOF. Several studies have demonstrated the prevalence of sustained episodes of tachyarrhythmias several years after intracardiac repair. In older rTOF patients, 34% develop symptomatic atrial or supraventricular tachycardias (SVTs), 8.5% develop high-grade VT, with an increasing number of implantable defibrillators being used due to a sudden-death estimate of 2% per decade. Thus, an estimated 50,000 adults with repaired ToF will require electrophysiology follow-up with 100 sudden deaths per year nationally (93). In a series of 242 patients, 29 (12%) developed sustained episodes of atrial tachyarrhythmia at a mean of 16 years after repair, while in another series, 29 of 793 (4%) had sustained atrial flutter or atrial fibrillation at a mean of 21 years after repair (94).

Therefore, life-threatening ventricular arrhythmias remain the greatest concern for the adult with rTOF. The incidence may be as high as 10%, and until the past decade, there were no consistently identifiable risk factors to consider which patients were at risk (95–99).
